- Samples must be collected from the source area(s). Samples must be collected to determine the full horizontal and vertical extent of soil contamination. Sampling should strive to characterize any horizontal or vertical stratigraphic variation at the site that could impact petroleum COI fate and transport. Where required to fully characterize the vertical extent of contamination, borings should be extended to the water table and features such as the capillary fringe and any smear zone, if encountered, should be characterized. Vertical sampling intervals generally should not be greater than 5 feet.
- Soil borings should be logged and samples for laboratory analyses collected in accordance with current industry practice.
- All samples must be adequately preserved according to requirements of the laboratory analyses and analyzed within holding times required by each method. Sample analyses must be conducted in accordance with current, EPA Office of Solid Waste and Emergency Response SW-846 Methods, or other accepted methods.
- Adequate QA/QC procedures must be used to ensure sample quality and integrity. Section 4.2.2 contains additional information on QA/QC considerations.
- All sampling equipment must be decontaminated using current state of industry practice such as described in ASTM D-5088-90, Practice for Decontamination of Field Equipment Used At Nonradioactive Waste Sites (ASTM, 1990).
- Abandonment of boreholes that extend to the water table, which are considered wells by IDWR, should follow IDWR abandonment procedures (IDAPA 37.03.09.16). Appropriate methodology for abandoning other boreholes is described in detail in the Standard Guide for Decommissioning Ground Water Wells, Vadose Zone Monitoring Devices, Boreholes, and Other Devices for Environmental Activities, Standard Guide D5299-99 (ASTM, 1999a).

4.2.8.1.3 Subsurface Soil vapor Data

At sites where petroleum COIs in soil or groundwater are volatile and there is concern about potential indoor inhalation of vapors, it may be useful to assess soil vapor concentrations. For details about these samples, refer to Appendix G (Evaluation of the Vapor Intrusion Pathway).

4.2.8.1.4 Logging of Soil Boreholes

Each soil boring must be logged to record depths correlating with changes in lithology (with lithologic descriptions), soil vapor (e.g., photo-ionization detector) analyses, occurrence of groundwater, total depth, visual and olfactory observations, and any other pertinent data.

When a monitoring well is installed, as-built diagrams with depth to groundwater and construction details must be submitted for each well. A continuous soil profile from at least one boring with detailed lithologic descriptions may be useful. Particular emphasis should be placed on characteristics that control chemical migration and distribution, such as zones of greater or lesser permeability, changes in lithology, correlation between soil vapor concentrations and different lithologic zones, obvious areas of soil discoloration, organic content, fractures, and other lithologic characteristics.

4.2.8.2 *Distribution of Petroleum Chemicals of Interest in Groundwater*

Adequate groundwater samples should be collected to delineate the extent of free product, dissolved contaminant plumes in all directions, maximum petroleum COI concentrations, and representative concentrations based on the SCM. This sampling should take into account knowledge of the soil source and the direction of groundwater flow.

4.2.8.2.1 Groundwater Sampling

If groundwater has been impacted, temporary sampling points may be used to screen levels of groundwater impacts and to assist in determining optimal locations of permanent monitoring wells. A sufficient number of monitoring wells should be installed to identify source areas and to document petroleum COI migration and groundwater flow. The monitoring wells should be installed in accordance with current IDWR rules (IDAPA 37.03.09) and industry standards such as ASTM D 5092-95, Standard Practice for Design and Installation of Ground Water Monitoring Wells in Aquifers (ASTM, 1995b). EPA documents such as the Resource Conservation and Recovery Act (RCRA) technical guidance for groundwater monitoring (EPA, 1986, 1992a) are also useful references.

Adequate numbers of monitoring wells must be installed to sufficiently delineate the horizontal and the vertical extent of the groundwater plume. The number and location of wells should also allow a site-specific estimate of the direction of groundwater flow. Well placement and design must consider the concentration of petroleum COIs in the source area, and the occurrence of NAPL at the site.

Well casing and screen materials must be properly selected. The screen interval length should be minimized to the extent possible but should be set at least 2 to 3 feet above the expected high water table and encompass the range of expected variation in water table depth. EPA (1992) recommends screen interval lengths of 10 to 15 feet except where specific monitoring objectives or site knowledge result in other requirements. Wells must be properly developed and gauged after installation. A site survey must be conducted to establish well casing elevations. Based on the groundwater elevations, groundwater flow direction and gradient should be determined and plotted on a map.

Groundwater samples must be collected in accordance with the following guidelines and procedures:

- Monitoring wells must be purged of an adequate number of well volumes prior to collecting a sample (usually 3 to 5 volumes). Low-flow purging and sampling techniques (EPA, 2002b) may also be acceptable when included in a DEQ-approved QAPP.
- Samples must be collected using EPA approved methods and equipment.
- All samples must be adequately preserved according to the requirements of the laboratory analyses and analyzed within holding times required by each method.
- Sample analyses must be conducted in accordance with EPA Office of Solid Waste and Emergency Response SW846 Methods, or other accepted methods.
- Adequate QA/QC procedures must be used to ensure sample quality and integrity. See section 4.2.2 for additional information on QA/QC considerations. All sampling equipment must be decontaminated using current state of industry practice such as

described in ASTM D-5088-90, Practice for Decontamination of Field Equipment Used At Nonradioactive Waste Sites (ASTM, 1990).

- If the plume is not delineated in all directions, locations of new monitoring wells must be chosen based on groundwater flow direction and location of the soil source area.

4.2.8.3 Surface Water and Sediment Sampling

Appropriate samples should be collected when petroleum COI migration is known or suspected to have impacted surface water. Water samples should be collected from upstream and downstream of a groundwater discharge point. Sediment samples should be collected if the SCM indicates a potential for releases to surface water.

In places where a groundwater plume may discharge into a stream, it is necessary to estimate the discharge concentration into the stream. This can be achieved by installing one or more monitoring wells or temporary wells within the plume adjacent to the stream.

4.3 Exposure Assessment

The goals of the exposure assessment portion of the RE are to:

- Characterize the physical setting,
- Identify potentially exposed populations,
- Identify complete or potentially complete exposure pathways,
- Estimate exposure concentrations, and
- Estimate petroleum chemical intakes.

The exposure assessment uses much of the data collected in support of and assumptions contained in the SCM (described earlier in section 4.1). A graphical display of the SCM like the sample shown in Figure 2 is helpful for assessing exposure.

4.3.1 Physical Setting

Characterization of the physical setting for exposure assessment identifies those site factors which may influence the fate and transport of chemicals from the source to a receptor. These factors include climate, meteorology, geologic and hydrogeologic setting, soil types, biodegradation potential, and surface water hydrology. When these factors are considered in the context of the media from which petroleum COIs are released (surficial soils, subsurface soils, groundwater, surface water, etc.), the transport mechanisms for the petroleum COIs from each media (leaching, groundwater transport, volatilization, etc.), and the chemical concentrations and distribution of the petroleum COIs in each media, the potential for a chemical to reach a receptor can be assessed. A more thorough discussion of the data needs related to description of the physical setting can be found in section 4.1 (Site Conceptual Model).

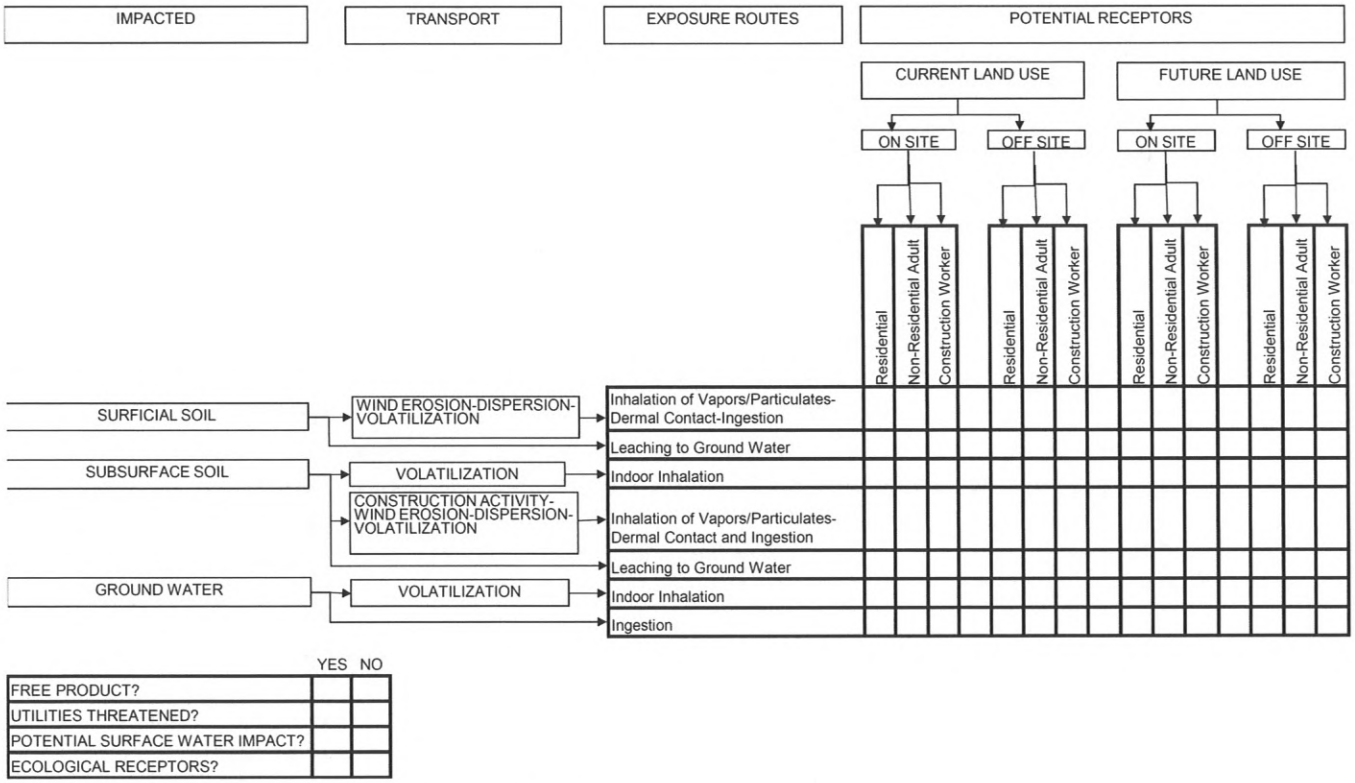

Figure 2. Sample Graphical Display of a Site Conceptual Model

4.3.2 Potentially Exposed Populations/Receptors

Potential exposure populations/receptors should be identified from the information contained in section 4.1 (Site Conceptual Model).

4.3.3 Exposure Pathways

A receptor comes in contact with petroleum COIs through a complete exposure pathway. If some but not all of the following elements are present, the pathway is incomplete. For a pathway to be complete, all of the following must be present:

1. a source of petroleum,
2. a mechanism by which the petroleum is released,
3. a transport medium through which petroleum travels from the point of release to the receptor location,
4. an ROE by which the petroleum chemical enters the receptor's body (ingestion, inhalation, or dermal contact) and
5. a potential receptor.

If the migration of petroleum chemicals to a receptor or contact by a receptor is not possible (e.g., due to formal engineering controls such as a paved site that will prevent human contact with petroleum-contaminated soil) under current and most likely future land use conditions, the site-specific petroleum COI concentrations may not pose a risk.

DEQ has identified the most commonly encountered exposure pathways for various environmental media for which an evaluation must be conducted. These pathways are discussed below. At sites where receptors, exposure pathways, or ROE other than those discussed below are important, the owner/operator must identify them and discuss their quantitative evaluation with DEQ. In some cases it may be determined that one or more of the pathways are incomplete and therefore do not need to be quantitatively evaluated. Adequate justification for exclusion of these pathways must be provided to and approved by DEQ.

4.3.3.1 Pathways for Surficial Soils (0–1 foot below ground surface)

Surficial soils are defined as soils extending from the surface to 1 foot below ground surface. For construction worker exposure, however, the applicable depth is the depth of excavation. The exposure pathways associated with impacted surficial soils include:

- Groundwater protection (leaching of petroleum chemicals from soil to groundwater with subsequent potential ingestion of groundwater),
- Surface water protection (leaching of petroleum chemicals from soil to groundwater with subsequent migration to a surface waterbody), and
- Ingestion of soil, outdoor inhalation of vapors and particulate emissions from soil, and dermal contact with soil.

4.3.3.2 Pathways for Subsurface Soils (1 foot below ground surface to the water table)

Subsurface soils are defined as soils extending from 1 foot below the ground surface to the water table. The exposure pathways associated with subsurface soils include:

- Indoor inhalation of vapor emissions from soil,
- Groundwater protection (leaching of petroleum chemicals from soil to groundwater with subsequent potential ingestion of groundwater), and
- Surface water protection (leaching of petroleum chemicals from soil to groundwater with subsequent migration to a surface waterbody).

4.3.3.3 Pathways for Groundwater

Potentially complete exposure pathways for impacted groundwater include:

- Indoor inhalation of vapor emissions from groundwater, and
- Current and/or future ingestion of water on or off site.

Appendix G describes in detail the process used to evaluate potential exposure via indoor inhalation of vapors from soil and groundwater.

4.3.3.4 Pathways for Surface Water and Sediments

Depending on the beneficial use designation of impacted surface waters, complete pathways for surface water include:

- Intentional ingestion of surface water and ingestion of fish when surface water is used as a drinking water supply, and
- Ingestion of fish from surface waters designated for recreational use.

4.3.3.5 Other Exposure Pathways

Other complete or potentially complete exposure pathways, such as ingestion of produce grown in impacted soils, ingestion of fish, contact with contaminated sediments, or use of groundwater for irrigation purposes, should be evaluated on a case-by-case basis. The owner/operator should contact DEQ for further guidance.

4.3.4 Exposure Point Concentrations

Exposure point concentrations are the average petroleum chemical concentrations to which receptors could be exposed over a specified duration within a specified geographical area. The geographical area about which a receptor moves and within which a receptor contacts contaminated media during the specified exposure duration is termed an exposure unit (EPA, 2001). The exposure unit of all receptors must be considered and described. The exposure unit, or spatial area over which a given receptor is likely to be exposed, must be established for on-site receptors as well as any off-site impacted or potentially impacted receptors and for each exposure pathway or ROE. The same site may have different exposure units for current and future use scenarios.

A detailed discussion of the estimation of exposure point concentrations and the use of exposure units for RE is provided in Appendix I. This appendix describes the sources of uncertainty which affect the estimation of exposure point concentrations, strategies to reduce this uncertainty, and methodologies to evaluate data quality. It also provides guidance on the selection of appropriate data for various ROE and appropriate statistical methods for analysis of available data.

The RE report should clearly identify specific data and methods used to estimate the exposure point concentrations, and provide a rationale for the method and data used. The following information should be provided in a table:

- Media
- ROE/pathway
- Receptor
- Data used
- Method of estimation

Table 3 shows how such a table might be constructed with examples of the type of information that would be supplied.

Table 3. Example Table Describing Derivation of Exposure Point Concentrations

Media	Route of Exposure	Receptor	Data Obtained From	Method
Surficial Soil	Direct Contact	Construction Worker	Unpaved Area	Average
Subsurface Soil	Indoor Inhalation	Commercial Worker	Building Footprint	Maximum
Groundwater	Ingestion	Residential	Source Area	Upper Confidence Limit
Soil Vapor	Indoor Inhalation	Commercial Worker	Sub-slab and near soil gas samples	Maximum

As presented in Table 3, an exposure point concentration is estimated for each complete ROE. Various methods available to estimate the exposure point concentrations are discussed in Appendix I. Use of the maximum concentration as the exposure point concentration is most conservative and also the easiest to calculate when compared with other ways of calculating exposure point concentration (average, area-weighted average, upper limit of the confidence interval around the mean). Thus, if the risk that is calculated using the maximum concentration is acceptable, considerable computational effort can be avoided.

4.3.4.1 Soil

Exposure point soil concentrations used to evaluate protection of the groundwater pathway should be calculated based on soil data collected within the source area only.

Soil data from the most recent investigation (assuming it was a comprehensive investigation) should be used. The use of older soil data (more than 4 years old), while discouraged, may be

acceptable if site conditions that would result in an increase in petroleum COI concentrations (such as a new release) have not changed. If a new release has or may have occurred, additional soil assessment activities that adequately characterize current conditions should be performed. New data collection efforts may be documented in a work plan and submitted for approval by DEQ.

4.3.4.2 Groundwater

Based on the SCM, several exposure point groundwater concentrations at a site may have to be estimated. These could include exposure point concentrations for the source area, at compliance locations, for protection of indoor inhalation on-site and off-site, and for off-site areas. Estimation of these concentrations will often require the use of fate and transport models, discussed in section 4.3.5.

In order to account for site-specific conditions such as source characteristics in relation to the depth to groundwater and the age of the release, it is typically necessary to perform multiple sampling events over time to ensure that the potential for the release to impact groundwater has been accounted for and that groundwater concentrations are representative. However, if these factors can be accounted for, it may be possible to perform an RE using data from one sampling event. If temporal data indicate significant variability, additional sampling events may be required prior to conducting the RE. Subsequent to RE, DEQ may require additional monitoring data to be collected. If recent groundwater data (less than one year old) is unavailable, current data may be necessary for the RE. The owner/operator may elect to document data collection objectives in a work plan submitted to DEQ for review and approval.

4.3.4.3 Point of Exposure and Point of Compliance

The point of exposure (POE) is the location where a receptor has or could come in contact with petroleum COIs under current and likely future conditions. A separate POE is associated with each complete exposure pathway-receptor combination identified in the SCM. For direct exposure pathways, the POE is located at the source of the petroleum COIs. For example, for the ingestion of surface soil, the POE is at the same location as the soil source. For indirect exposure pathways, the POE and the source of petroleum COIs are physically separate. For example, for the case of indoor inhalation of vapors from soil, the POE is inside the building (the breathing space) whereas the source is the soil below and adjacent to the building. The POE location for the protection of the groundwater for groundwater ingestion is discussed in section 4.3.3.3.

A point of compliance (POC) is a location where concentrations are measured to determine if compliance with remedial goals has been achieved. Concentration measurements at the POC may be in any media (e.g., soil, groundwater, soil vapor, etc.). The location of a POC may be identical to the POE or may be located between the source and the POE. In the latter case, the target concentrations at the POC are back-calculated to ensure that the concentrations at the POE do not exceed the target concentration at the POE. For example, for the protection of the groundwater pathway, the POC well may serve as a sentry well for protection of the POE. The calculated target levels for the POC are then compared to measured concentrations. POC locations may be predetermined based on program-specific requirements. Most sites, particularly those involving groundwater impacts, will have multiple POC locations.

4.3.4.4 Estimating Point of Compliance Well Concentrations

As a part of the RE process, it is necessary to designate and monitor appropriate POCs. The POCs, located onsite and/or offsite, are used to provide additional assurance that approved concentrations at a selected POE are not exceeded. Monitoring of POC locations is required, and data obtained are compared with approved RATL concentrations. Monitoring of POC locations must be continued until the concentrations stabilize below approved levels. Concentrations at the POC may also be used to determine the need for additional remedial activities.

4.3.5 Fate and Transport and Exposure Models

Different types of models or equations, uptake equations, risk equations, and fate and transport models, are required to calculate chemical intake, risk, exposure point concentrations, and target concentrations. Fate and transport models simulate the transfer of chemicals from one media (such as soil) to another (air). They also are used to simulate the movement of chemicals within a given media, such as the transport of chemicals in groundwater from a source area to a POE. They allow the estimation of concentrations at points distant from the source. A schematic and the equations for each of these models are presented in Appendix E. DEQ has selected the following default fate and transport models:

Indoor Inhalation of Volatile Emissions from Soil and Water: This pathway requires an emissions model and an indoor air-mixing model. These models are combined together and included in the Johnson and Ettinger Model (Johnson and Ettinger, 1991; EPA, 2003). The Johnson and Ettinger Model does not include the effects of attenuation by biodegradation, which may be significant for petroleum COI.

Surficial Soil Outdoor Inhalation: This pathway requires an emissions model for vapors, an emissions model for particulates, and an outdoor air-mixing model. The vapor emissions model used is based on the volatilization model developed by Jury et al. (1983) for an infinite source, the particulate emissions model is the Cowherd model (Cowherd, et al., 1985), and the outdoor air-mixing model is based on a simplified form of the Gaussian Dispersion model. These models are presented in Soil Screening Guidance: Technical Background Document (EPA, 1996a).

Leaching to Groundwater: This pathway uses a three-phase equilibrium partitioning equation to convert soil concentrations to leachate concentrations. These leachate concentrations are then used with a dilution attenuation model to simulate mixing of leachate with regional groundwater. Models used are described in Soil Screening Guidance: Technical Background Document (EPA, 1996).

Horizontal Migration in Groundwater: The Domenico steady-state analytical infinite-source model is used to quantify down-gradient migration of chemicals (Domenico, 1982, 1990). This model incorporates the processes of advection, sorption, three-dimensional dispersion, and degradation.

Alternative models may be used with prior DEQ approval.

4.3.5.1 Fate and Transport Parameters

Fate and transport parameters are necessary in the models used to estimate exposure point concentrations and compliance point concentrations for indirect pathways such as vapor intrusion and protection of groundwater. These parameters characterize the physical site properties such as depth to groundwater, soil porosity, and infiltration rate. DEQ has selected the conservative default values listed in Appendix B. Justification for these parameters is included in Appendix B. For RE, a combination of site-specific and default values for these parameters is typically used. However, the value of each parameter used, whether site-specific or default, must be justified based on site-specific conditions. Where fate and transport models other than those selected by DEQ are used, the specific fate and transport parameters required to calculate exposure point concentrations and risk may vary and have specific data collection requirements.

4.3.5.2 Physical and Chemical Properties of the Petroleum Chemicals of Interest

The development of target levels requires the selection of values for the physical and chemical properties of petroleum COIs. Values of these parameters are listed in Appendix C. To use different values, the owner/operator must provide sufficient justification to DEQ. The use of different values will be allowed only with prior DEQ approval. DEQ will update the data in Appendix C as new information becomes available.

4.3.6 Estimation of Chemical Intake

Risk evaluation requires quantifying the magnitude, frequency, and duration of exposure for the receptor populations and exposure pathways selected for analysis. Oral exposures are quantified on a dose per unit body weight basis while inhalation exposure is based on concentration in air.

4.3.6.1 Exposure Factors

In order to determine receptor and pathway-specific intake estimates, it is necessary to select values for a number of exposure parameters in the equations used to calculate intake. The selection of values for the following parameters is based on an assessment of recommendations in various guidance documents, as well as the open scientific literature. When determining these values, it is often necessary to make assumptions. Details and rationale regarding these assumptions are provided in Appendix A. Exposure assumptions for surface water related pathways are incorporated into the toxics criteria for surface water discussed in section 4.6.

Exposure factors describe the physiological and behavioral characteristics of the receptor. These factors include the following:

- Water ingestion rate,
- Body weight,
- Exposure duration for each ROE,
- Exposure frequency,
- Soil ingestion rate,
- Exposure times for indoor/outdoor inhalation,
- Dermal relative absorption factor,

- Skin surface area for dermal contact with soil,
- Soil-skin adherence factor, and
- Oral relative absorption factor.

A list of default exposure factors values selected by DEQ and justification for their choice is presented in Appendix A. Site-specific values of exposure factors, other than default values, may be used. However, the owner/operator must submit a proposal for the use of alternative values to DEQ for approval, and approval must be obtained before using alternative values for exposure factors.

4.4 Toxicity Assessment

4.4.1 Chemical-Specific Toxicological Factors

The toxicity of chemicals with carcinogenic adverse health effects is quantified using cancer slope factors (CSF) for oral and dermal ROE, or inhalation unit risk (IUR) for the inhalation route. A CSF is an upper-bound estimate of the probability of a response (developing cancer) per unit intake of a chemical over a lifetime. The IUR is the upper-bound excess cancer risk estimated to result from continuous exposure to a chemical at a concentration of 1 $\mu g/m^3$ in air.

For chemicals that cause noncarcinogenic health effects, toxicity is typically quantified by reference doses (RfD) for oral and dermal ROE, and reference concentrations (RfC) for the inhalation ROE. The RfD is an estimate of a daily oral exposure to the human population (including sensitive subgroups) that is likely to be without risk of adverse health effects during a lifetime. Since RfDs are based on oral exposure, they are modified for use in dermal exposure assessment to take account of differences between gastrointestinal and dermal absorption. The RfC is an estimate of a continuous inhalation exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of adverse health effects over a lifetime.

The primary source of information for toxicity factors for the petroleum COI is the EPA RSL tables (RSL) (EPA, 2018) found at:
http://www.epa.gov/reg3hwmd/risk/human/rb-concentration_table/index.htm

Toxicity factors selected by DEQ for the petroleum COIs are presented in Appendix D.

Table 4. Default Toxicity Values for Risk Evaluation.

DEFAULT TOXICITY VALUES FOR RISK EVALUATION

4.4.2 Carcinogens with a Mutagenic Mode of Action

Current EPA guidance for risk assessment of carcinogens addresses the potential for increased susceptibility to cancer from exposure to carcinogens that occurs early in life (EPA, 2005a; EPA, 2005b). When information is available to establish the mode of action of a chemical for early-life and adult exposures, it may be appropriate to develop separate risk estimates for childhood exposure and exposure occurring later in life. When the mode of action cannot be established, risk estimates are based on a lifetime daily average exposure without adjustment. Currently, there is sufficient information to develop separate risk estimates only for chemicals having a mutagenic mode of action.

Specifically, when data indicate a mutagenic mode of action for a chemical, meaning that the chemical interacts directly with DNA, available studies indicate higher cancer risk for a given exposure when it occurs early in life compared to a similar exposure in adulthood. Among the petroleum chemicals of interest, the following carcinogenic chemicals are considered mutagens:

- Benzo(a)anthracene
- Benzo(a)pyrene
- Benzo(b)fluoranthene
- Benzo(k)fluoranthene
- Chrysene

For these chemicals, the following adjustments are made to risk estimates:

- For exposures between birth and two years of age, a ten-fold adjustment (multiplication factor) is applied. Toxicokinetic and toxicodynamic differences between children and adults are greatest for this age group.
- For exposures occurring to those in the age categories of two to six years of age and between six and sixteen years of age, a three-fold adjustment is applied.
- For exposures occurring after 16 years of age, no adjustment is applied.

These adjustments are combined with corresponding age-specific exposure parameters to assess cancer risk. For a standard residential exposure scenario of 30 years, a ten-fold adjustment is made for the first two years, a three-fold adjustment is made for the next fourteen years, and no adjustment is made for the final fourteen years of the exposure period.

The screening levels are based on unrestricted (residential) exposure; therefore they incorporate the adjustments described here. The effect of the adjustments will be a somewhat higher estimate of risk for a given exposure (and thus somewhat lower screening levels) compared to risk estimates without age-specific adjustment. Calculated risk estimates for residential exposure will incorporate these adjustments, but nonresidential risk estimates will not, as they are based on adult exposure.

4.5 Risk Characterization

The process of risk characterization consists of combining the intake estimates developed through the exposure assessment and toxicity information for the petroleum COIs and calculating carcinogenic risk and noncarcinogenic hazard. Calculations are made for each pathway-receptor combination and are summed to calculate a cumulative risk and a hazard index (HI) for each receptor. These risk results are then presented and discussed in a risk summary and are compared to acceptable target risk levels.

Risk and hazard calculations are completed using a standard set of risk equations provided by the EPA in their User's Guide for RSLs (EPA, 2012) and presented in Appendix E. Estimates made using these equations should be presented using one significant figure, although an additional significant digit should be carried through the supporting calculations, such as when summing risks from multiple petroleum chemicals or pathways, in order to minimize rounding errors. For example, calculated cancer risks would be presented as $1 \times 10^{-4}$and HQs or HIs would be expressed as 2, 0.7, or 0.03.

This risk-based decision-making process specifies the acceptable risk levels for both carcinogenic and noncarcinogenic health effects. For carcinogenic effects, risk is quantified using the individual excess lifetime cancer risk (IELCR) that represents an increase over background in the probability of an individual developing cancer due to exposure to specific petroleum COI through a specific exposure pathway. Since a receptor may be exposed to multiple petroleum chemicals through multiple ROEs, the acceptable risk level should account for the effect of simultaneous exposure to multiple petroleum chemicals and multiple ROEs. Overall site carcinogenic risk is calculated as the sum of the individual chemical risk estimates. The probability of a receptor getting cancer is thus the sum of the probabilities of getting cancer from exposure to each petroleum chemical through each exposure route. In this calculation there is an assumption of independence of action of the individual chemicals. If the carcinogenic actions of different petroleum chemicals are not independent there is the possibility of synergistic interaction in which case risk may be underestimated. However, information is generally not available to address this possibility.

For noncarcinogenic effects, risk is quantified using an HQ that represents the ratio of the estimated dose of a petroleum chemical for a ROE to the reference or allowable dose. When a

receptor is exposed to multiple chemicals and multiple ROEs, individual HQs are added together to estimate the HI.

For site-specific REs, the following target risk criteria must be satisfied at the POE:

Acceptable Target Risk Level: For combined exposure to all carcinogens and ROE, IELCR must be less than or equal to $1x10^{-5}$ for a receptor at a reasonable maximum exposure.

Acceptable HI: The summation of HQs for all petroleum chemicals that have noncarcinogenic health effects and ROE must be less than or equal to 1.

The target risk level and HI must be met for each current and potential future receptor at the site. If the initial calculated HI exceeds 1 further evaluation, including analysis of mode of action and target organ for each petroleum chemical, can be completed. If this analysis indicates sufficient independence of target organs and mode of action for different chemicals, it may be acceptable to present separate HQs, and/or one or more HI for subsets of the chemicals. This kind of analysis should be performed by a toxicologist.

In addition to the target risk levels, DEQ requires that MCLs, or comparable risk-based values for groundwater ingestion, be met at the POE when there is a high probability of groundwater use. When there is a low probability of groundwater use for drinking water, alternate risk-based groundwater target concentrations, based on the other potentially complete exposure pathways identified for the site, must be met at the POE. Similarly, for impacts to surface water bodies, calculated target concentrations must be met.

The risk summary should include an analysis and discussion of the sources of uncertainty so that the risk estimates can be placed in perspective. The uncertainty analysis can be qualitative or quantitative in nature. It is more important during the analysis to identify the key site-related parameters and assumptions in the SCM that contribute the most to the uncertainty than to precisely quantify the degree of uncertainty (EPA, 1989). It is typically the case that there is insufficient information available at a given site to be able to reliably quantify the uncertainty in a given risk estimate, such as through conducting a probabilistic risk assessment or sensitivity analysis. The typical sources of uncertainty that are included in the analysis include the petroleum COIs selected and their estimated site concentrations, the toxicity values used, the fate and transport models used to estimate exposure point concentrations, the exposure parameter values used in the exposure assessment, and the summing of risks from multiple pathways or petroleum chemicals.

4.6 Risk-Based Target Levels

As described in the Risk Characterization section 4.5, if the calculated risk or hazard for all petroleum COIs and complete ROE for identified potential receptors exceeds the Acceptable Target Risk or Hazard Levels and corrective action is required, then risk-based target concentrations (RATLs) to achieve these targets should be calculated. Ingestion of water is not included in this calculation. The procedure used to calculate RATLs requires chemical-specific toxicological factors, receptor-specific exposure factors, fate and transport parameters, physical and chemical properties of the petroleum COIs, and mathematical models. In calculating risk-

based target concentrations, all of these factors, properties, and models are typically the same as used for calculations of other risk-based levels.

Target concentrations should be estimated using an allocated risk process that apportions the acceptable target cumulative risk and HI among the different chemical-pathway combinations. The primary goal is to develop target concentrations in all media such that the acceptable target risk levels and hazard levels are met. There is no standard way to apportion the cumulative risk. To develop RATL concentrations, the default option selected by DEQ apportions cumulative risk and HI equally among all contributing petroleum chemical-pathway combinations such that those petroleum chemicals which contribute the greatest proportion of the total risk have the most stringent remediation standards. This methodology is described in detail, with examples, in Appendix D and is implemented in the computational software provided by DEQ to complement this guidance.

If a petroleum COI has toxicity that is based on both carcinogenic and noncarcinogenic effects, the applicable RATL for that chemical should be the lower of the two calculated allowable concentrations.

Site-specific considerations may result in an owner/operator choosing to utilize a different method for calculating target concentrations. For example, at a site having volatile and semi-volatile petroleum COIs contributing to the cumulative risk, the owner/operator may choose a technology that specifically reduces the volatile chemical's concentrations but marginally reduces the concentration of the semi-volatile chemical. A different owner/operator may choose to significantly reduce the concentration of the semi-volatile chemical and marginally reduce the concentration of the volatile chemical. The two strategies will result in different cleanup levels for each chemical; however, both will be acceptable provided cumulative risk meets the acceptable target risk criteria.

4.6.1 Developing RATL Concentrations for Groundwater and Surface Water Protection

For groundwater and surface water protection, target concentrations are calculated using somewhat different procedures, described below.

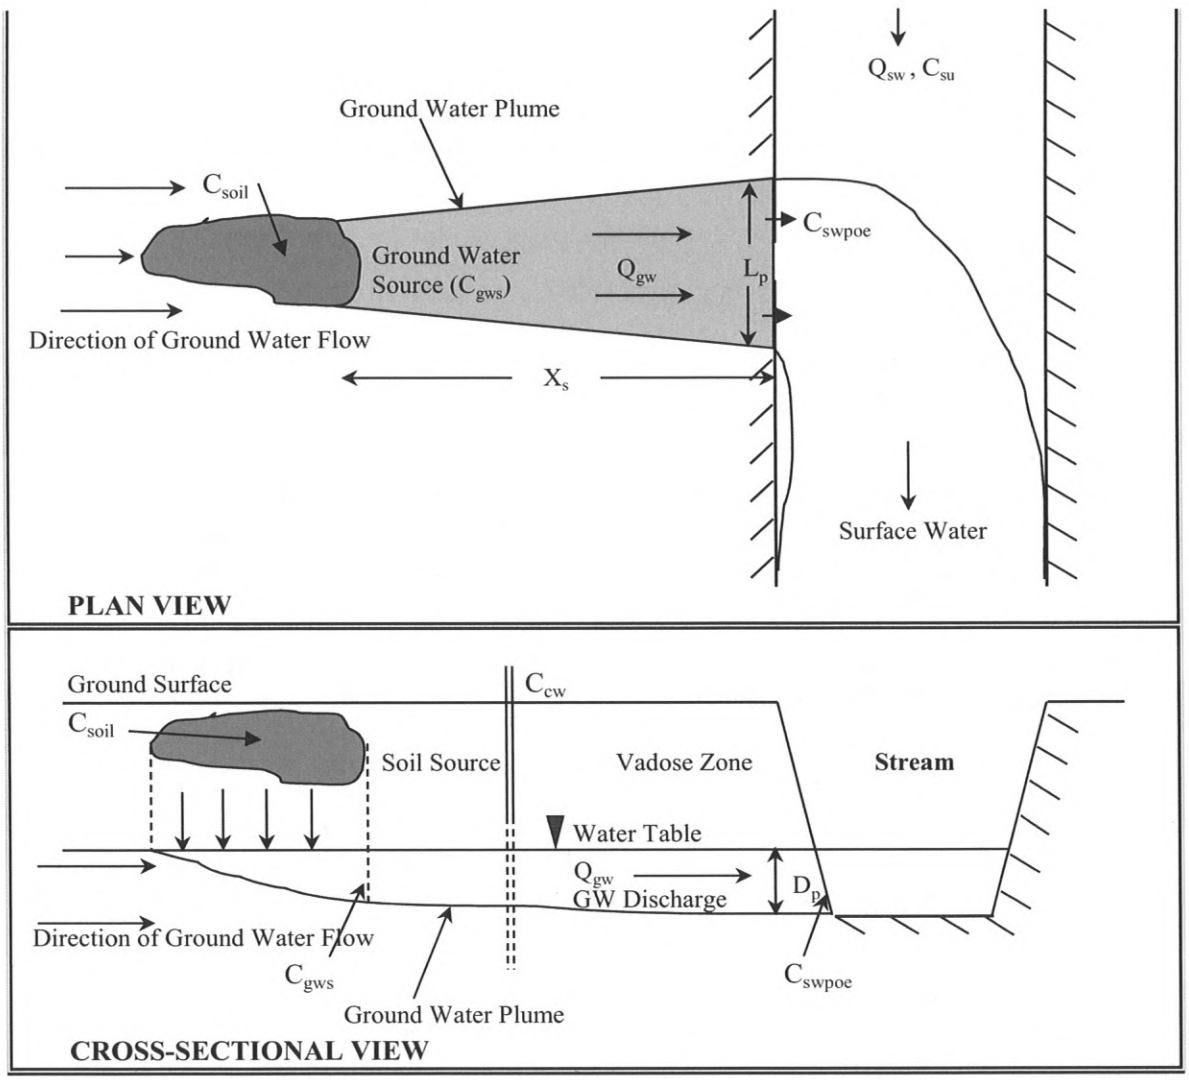
4.6.1.1 Groundwater Protection

The RATL concentrations for groundwater ingestion are equivalent to the federal MCLs or a risk-based calculated equivalent. MCLs are health-protective target concentrations promulgated by the EPA and adopted by the state of Idaho for the protection of drinking water and specified groundwater resources. For any petroleum COI that has an MCL, the RATL concentration for groundwater ingestion is equal to the MCL. For any petroleum COI that does not have an MCL, the risk-based equivalent level is calculated using the following input values and equations:

- A target risk level of $1x10^{-6}$ for carcinogenic effects and an HQ of 1 for noncarcinogenic effects,
- The residential exposure factors in Appendix A,
- The toxicity values in Appendix D, and
- Risk equations for the direct ingestion of water.

Calculations are made for residential receptors.

The RATL concentrations will apply at the POE. The POE will be the down-gradient property boundary, as it existed when the release occurred, or the nearest down-gradient location where a well exists or could be reasonably placed. Depending on site-specific conditions it is also possible to have multiple points of exposure.



4.6.1.2 Surface Water Protection

Potential impacts to streams and other surface waterbodies from a petroleum release must be evaluated and surface water quality must be protected as per IDAPA 58.01.02 (Water Quality Standards and Wastewater Treatment Requirements). The primary receptors and ROE for potentially impacted surface waters evaluated in the RE process are described in section 4.6.1.2.1. Other ROE, such as contact with contaminated sediments or overland flow discharge, are evaluated on a case-by-case basis.

This section describes the evaluation of potential impacts to surface water via discharge of impacted groundwater to a surface waterbody. A schematic illustrating this exposure pathway is shown in Figure 3. This figure shows the relevant compliance and exposure locations and associated concentrations. Within the RE process, protection of surface waterbodies requires the owner/operator to determine or calculate the applicable surface water standards at the point where groundwater discharges into a surface waterbody (C_{swpoe}). Once the appropriate surface water standard is determined, compliance with the standard may be achieved in a number of ways. These include measuring surface water concentrations at the point of groundwater discharge, measuring groundwater concentrations at the point of discharge into the surface waterbody, or determining appropriate alternate concentrations in other media and at POC locations. Selection of alternate locations may be most appropriate for those sites where contamination has not yet reached a surface waterbody. Alternate concentrations (or RATLs) and POC locations can include:

- Source area soils (C_{soil}), or
- Compliance points in groundwater at different distances between the surface water and the source (C_{cw}) other than the point where groundwater discharges into the surface waterbody.

The owner/operator can back-calculate allowable soil (C_{soil}) and compliance well concentrations (C_{cw}) using dilution attenuation factors (DAFs). Specific equations, combining the Summer's mixing model and the Domenico analytical groundwater transport model, are presented in Appendix E. If measured concentration(s) at the soil source or the compliance well exceeds corresponding allowable concentrations, cleanup to RATL concentrations or performance of a more detailed, site-specific evaluation to refine DAFs are options.

Explanation of Symbols

Q_{sw} = Stream flow upstream of the point of ground water discharge
C_{su} = Concentration upstream of the ground water discharge
Q_{gw} = Impacted ground water discharge into the stream
C_{sw} = Allowable downstream concentration after uniform mixing
C_{swpoe} = Allowable concentration at the point of ground water discharge to the stream
C_{gws} = Allowable concentration in the ground water at the edge of the soil source
C_{soil} = Allowable soil concentration at the source protective of the stream
C_{cw} = Allowable soil concentration in ground water at different distances between the stream and the source
L_p = Width of ground water plume discharging to the stream
D_p = Thickness of ground water plume discharging to the stream
X_s = Distance from the downgradient edge of the ground water source to the stream

Figure 3. Schematic of Leachate Migration from the Soil Source to the Stream

4.6.1.2.1 Surface Water Quality Standards

The allowable concentration at the point of groundwater discharge into the surface water (C_{swpoe}), or the surface water quality standard, depends on the beneficial use designations of the surface waterbody as per IDAPA 58.01.02.100 and criteria assigned to protect those beneficial uses (IDAPA 58.01.02.200-250).

Beneficial uses include:

- Aquatic life: Cold water, salmonid spawning, seasonal cold water, warm water, or modified.
- Recreation: Primary contact or secondary contact.
- Water supply: Domestic, agricultural, or industrial.

Each beneficial use has associated numerical and narrative criteria. Numerical criteria are specified values that are not to be exceeded. For narrative criteria involving toxic substances, concentrations are not specified, but must be low enough to ensure that designated beneficial uses are not impaired. When necessary, development of numeric criteria for toxic substances is governed by IDAPA 58.01.02.210.05.

The allowable concentrations for certain toxic substances associated with these beneficial uses are tabulated in IDAPA 58.01.02.210.01.b .

4.6.2 Determination of Applicable Risk Based Levels

The calculated allowable RATL concentrations for protection of groundwater and/or surface water and those calculated for other potentially complete exposure pathways are compared to determine which media-specific concentrations will guide the cleanup. Typically, the lower of these concentrations will be selected.

Using groundwater as an example, target POE concentrations will be based on the most limiting concentrations determined from evaluation of the complete or potentially complete pathways in addition to the groundwater ingestion pathway. These pathways may include indoor inhalation of vapors volatilized from groundwater, groundwater impacts to surface water, impacts to deeper groundwater systems with the potential for use as drinking water supplies, and also incidental ingestion of and dermal exposure from irrigation water. Also included is potential impairment of other beneficial uses of groundwater such as for agricultural or industrial water supplies.

The applicable POE will be based on the location of the plume (on-site vs. off-site) and which pathway(s) and receptors are limiting with respect to risk and allowable groundwater concentration. In many cases, particularly if a plume has migrated off-site, there may be multiple POE and pathways that will need to be considered.

For example, a petroleum-sourced volatile organic compound (VOC) plume may have migrated off-site into a residential area and have the potential to discharge to a down-gradient stream. Source area groundwater concentrations on-site must be controlled such that concentrations at the POE where groundwater discharges to the stream meet applicable criteria. In addition, unless vapor intrusion has been separately addressed, such as through the use of soil vapor, residential

vapor intrusion criteria in groundwater would need to be met at the down-gradient boundary of the source property and commercial criteria for on-site POE.

4.7 Deliverables

The primary deliverables associated with conducting a site-specific RE typically include an optional work plan for the collection and evaluation of data, an optional data collection report, and the required RE report. In many cases, the results of a data collection effort are combined with the RE report. If the results of the RE report indicate the need for corrective action, a CAP must also be developed and submitted. The contents of CAPs are discussed in Section 5. This section describes the contents of a work plan.

4.7.1 Work Plan

A work plan may be desirable where extensive data collection activities or significant departures from default exposure assumptions or modeling are being proposed.

As appropriate, a work plan to fill identified data gaps may be prepared and submitted to DEQ for review. The amount of detail to be included in the work plan will vary among sites. At sites where a considerable amount of data has already been collected, the work plan may be a brief letter indicating activities to be performed to fill in the data gaps. For a complex or large site, a very detailed work plan, including the SCM, data collection methodology, analysis methods, a data QAPP, and a health and safety plan may need to be developed.

An RE work plan should address each item discussed in sections 4.7.1.1 through 4.7.1.11 as appropriate to the purpose and goals of the RE.

4.7.1.1 Purpose and Goals

The purpose and goals of the work plan should be clearly stated. If the purpose is to fill data gaps, then a listing and description of the data gaps should be provided along with an explanation as to why they constitute data gaps and how the work proposed will fill those gaps.

If the purpose of the work plan is to propose use of alternative models, exposure factors, physical and chemical properties, toxicity factors, or methods of calculating remedial target concentrations, then a rationale should be provided as to why the alternatives proposed are needed. A short description of the scope and nature of the work proposed should be provided.

4.7.1.2 Site Background

This portion of the work plan may refer to documents previously submitted to DEQ; it is not necessary to repeat the entire site background description. Reference should be made to document(s) that contain a comprehensive chronology of site investigations.

4.7.1.3 Site Conceptual Model

A concise summary of the existing SCM should be provided. In those cases where the goal of the work plan is to revise a previously completed RE, then an SCM already exists that can be referenced rather than repeated. If validation or revision of a previous SCM is necessary, those

aspects of the current SCM that are the target of the work plan should be described. Refer to section 4.1 for the suggested content of the SCM.

4.7.1.4 Exposure Factors

If alternate exposure factors values are proposed in the work plan these factors must be justified and acceptable to DEQ. The default exposure factor values are listed in Appendix A.

4.7.1.5 Physical and Chemical Properties

Owner/operators should use the default physical and chemical properties for the petroleum COIs as listed in Appendix C.

4.7.1.6 Toxicity

The Rule specifies that toxicity values for petroleum chemicals listed in Appendix D must be used in the RE.

If additional chemicals need to be included in the RE, as provided for in Section 100.02 of the Rule, their physical chemical properties and toxicity values should be obtained from the EPA RSL website (EPA, 2018).

4.7.1.7 Fate and Transport Models

If alternative models are being proposed, the work plan should include reasons for using alternative models; it should demonstrate that the proposed models will better simulate site-specific conditions, and that the sufficient site-specific data are available or will be collected to justify the use of the proposed model. Alternative models must be approved by DEQ before they are used.

4.7.1.8 Fate and Transport Parameters

Data collection may be proposed to collect site-specific values in lieu of using DEQ default values for fate and transport parameters (listed in Appendix B) used in models for the RE. The parameters for which values are to be obtained should be specified and the methodology used to obtain those values described.

DEQ accepts the use of chemical-specific biological decay rates or attenuation factors in the fate and transport models. Use of decay rates in a RE must use values supported by site-specific information. Refer to Appendices G and H for data necessary to demonstrate occurrence of natural attenuation and methods to calculate decay rates. Examples of this type of information include, but are not limited to:

- Consistent stable or decreasing concentration (above the Residential Use Screening Levels [RUSLs]) trends in properly located and constructed monitoring wells, and
- Measurements of natural attenuation parameters that provide evidence of biodegradation.

4.7.1.9 Calculating RATL Concentrations

The process of calculating target concentrations (RATLs) is described in section 4.6 and Appendix F. If a method of apportioning risk and calculating RATLs different than the DEQ

default method is desired, the proposed methodology and rationale for the choice should be described.

4.7.1.10 Methodology and Quality Control

Work plans in support of data collection efforts should describe the methodology that will be used to obtain the data and provide a clear description of the level of data quality required to meet the stated objectives, and how this data quality will be achieved and ensured.

4.7.1.11 Schedule and Deliverables

The optional work plan should include an overall project schedule and deliverables that will be submitted to DEQ. The schedule should include any agency meetings necessary during work plan implementation.

4.7.2 Implementing the Work Plan

Upon receipt of a work plan approval, the owner/operator should implement the work plan according to the schedule in the work plan. In case there are delays, it is the owner/operator's duty to inform DEQ of the delay and revised schedule. If there were deviations in the work performed from that specified in the approved work plan, DEQ should be notified of the deviations and their impact on the goals and purposes of the work plan.

Upon completion of work specified in the work plan, the owner/operator should document the results and submit them to DEQ. If the purpose of the work plan included data collection, the data collection results can be summarized in a separate data collection report or incorporated into a revised RE report.

4.7.3 Risk Evaluation Report

The RE for a site must be clearly and concisely documented and submitted to DEQ for review. An example outline of an RE report is presented in Appendix J.

Section 5. Developing and Implementing Corrective Action Plans

Development and implementation of a CAP may be necessary if, after the screening level evaluation or site-specific RE, concentrations exceed screening levels or an unacceptable risk is identified and the owner/operator has chosen not to perform additional evaluation. The owner/operator must then develop cleanup criteria (also referred to as remediation standards) and create a CAP to achieve those standards or to ensure that the remaining risk is acceptable. The risk management strategy described in the CAP depends on the results of the RE (which pathways, petroleum chemicals, and media are responsible for the unacceptable risk) and other circumstances unique to the site.

5.1 Contents of a Corrective Action Plan

As required in the Rule, the CAP must include:

- A description of remediation standards selected, points of exposure, and points of compliance,
- A description of the remedial strategy and actions to be taken to achieve the remediation standards,
- Current and future land use and use of groundwater and surface water both onsite and offsite,
- AULs that will be required as part of the remedial strategy and the associated environmental covenants,
- Estimated timeline for completion of remedial actions,
- The monitoring plan to gauge effectiveness of the remedial strategy, and
- A description of practical quantitation limits and background concentrations as they apply to the remediation.

Additional elements that should also be a part of the plan include:

- A brief site description,
- A brief description of the RE approved by DEQ, including assumptions used for receptors and land use, and a list of approved cleanup levels for specific pathways, media, chemicals, and specific areas of the site (if applicable),
- A clear description of reasons a CAP is needed,
- An identification of the area(s) to be managed under the CAP,
- A description of the strategy selected to achieve cleanup goals, including a comparison and evaluation of remedial alternatives considered in development of the overall strategy. A rationale for the strategy selected should be presented; any data collected in support of or to determine the feasibility of a particular remedial measure such as pilot testing, should be presented,
- A description of what QA/QC measures will be implemented to ensure that data collected in support of remedial decision making is of adequate quality,
- A description of project closure requirements, and
- A reporting schedule to document progress of the corrective action.

5.2 Implementing a Corrective Action Plan

The CAP should not be implemented until approved by DEQ. Within 30 days of receiving a CAP, DEQ must provide an approval, an approval with modifications, or a rejection (specifying reasons for the rejection) in writing. Provisions are made in the Rule (Section 200.04) for extending this timeframe.

While DEQ is reviewing the CAP, implementation of interim corrective action measures may take place. However, as provided in IDAPA 58.01.02.852.06.c, owner/operators may, in the interest of minimizing environmental contamination and promoting more effective cleanup, begin cleanup of soil, surface water, and groundwater before the CAP is approved provided that they fulfill certain conditions including:

- Notifying DEQ of their intention to begin cleanup;
- Compliance with any conditions imposed by DEQ, including halting cleanup or mitigating adverse consequences from cleanup activities; and

- Incorporation of these self-initiated cleanup measures in the CAP that is submitted to DEQ for approval.

Typical interim corrective actions include excavating and disposing contaminated soil, removing free product, extracting soil vapor, and pumping and treating groundwater.

Upon approval of the CAP, the owner/operator must implement the plan according to the proposed schedule. All performance data should be submitted to DEQ in a timely manner. This data should be carefully evaluated by both the owner/operator and DEQ to determine if the CAP is progressing as anticipated. Major deviations in schedule or plan implementation should be communicated to DEQ for review and approval well in advance of proposed implementation, along with recommended modifications if necessary. The specific modifications that may be needed will vary from site to site.

When the CAP has been successfully implemented, the owner/operator should document these conditions in a completion report along with a petition to DEQ for site closure.

Section 6. Activity and Use Limitations

An AUL is a restriction or obligation, with respect to real property, that is created by an Environmental Covenant pursuant to the Uniform Environmental Covenants Act (UECA), Chapter 30, Title 55, Idaho Code. It is available at: *http://legislature.idaho.gov/idstat/Title55/T55CH30.htm*

The purpose of AULs is to reduce the potential for exposure to contaminants at a release site. AULs are also commonly referred to as "institutional controls." AULs are typically proposed to DEQ for approval through the RE process. Non-remedial land use restrictions (e.g., local zoning ordinances) may reinforce the sustainability of AULs; however, they are not considered sufficient by themselves. These types of non-remedial land use restrictions, such as zoning ordinances, may change or be removed without DEQ approval and therefore are not approved by DEQ as part of a CAP. However, non-remedial land use restrictions may be relevant to evaluating current and reasonably likely future use and exposure scenarios at a site.

6.1 Environmental Covenants

Owner/operators may propose an Environmental Covenant as part of the CAP which will include the AUL language. Any proposed Environmental Covenant must be consistent with UECA. Each proposed Environmental Covenant is reviewed and evaluated on a site specific basis.

Following is a *non-exclusive* list of the types of activity and use limitations that may be included in an Environmental Covenant:

- Restrictions on Water Use:
  - Prohibit use
  - Limit use
  - Monitor use
  - Report use
  - Operation and maintenance procedures for physical controls and devices
  - Prohibit well installation and operation
  - Abandon an existing well.
- Restrictions on Land Use:
  - Prohibit, or require DEQ approval for, disturbance of soil, cap, or vegetation
  - Limit activities and land use
  - Limit structures and buildings.
- Actions Regarding Access:
  - Right of Access necessary to implement the activity and use limitation
  - Limit or deny public access.
- Obligations to perform certain actions in order to maintain the effectiveness of an approved corrective action. For example, this may involve the need to do periodic inspections and maintenance in order to ensure that a cover or barrier retains its primary

REC 4564

TR 1249

function. In this case there might be a specific reference in the Environmental Covenant to an Operations and Maintenance Plan, developed as part of the corrective action.

DEQ has an Environmental Covenant template that owner/operators can use when proposing activity and use limitations as part of a CAP. The DEQ website includes a copy of the latest Environmental Covenant template at *http://www.deq.idaho.gov/environmental-covenants*. The owner/operator can propose an environmental covenant consistent with UECA for consideration and approval by DEQ.

6.2 Specific Application of Activity and Use Limitations at Petroleum Release Sites

Section 600.01 of the Rule outlines the circumstances under which AULs will be included as part of a CAP. These include:

- Where the assumed onsite land use for the purpose of the RE is not residential and either the maximum media concentrations exceed the screening levels or the calculated risk for a residential receptor is unacceptable
- Where off-site groundwater concentrations exceed RUSLs or risk-based concentrations, and
- Where DEQ determines, based on the proposed CAP, that such AULs are required to assure the continued protection of human health and the environment or the integrity of the cleanup action.

6.3 Use of Activity and Use Limitations at Impacted Neighboring Properties

Implementability and enforceability issues become more complicated when an owner/operator proposes use of AULs on impacted neighboring properties. It is the owner/operators's obligation to negotiate language and reach agreement with both the impacted property owner and DEQ.

6.4 Non-Remedial Land Use Restrictions

Non-remedial land use restrictions (e.g., local zoning ordinances) may reinforce the sustainability of AULs; however, they are not considered sufficient by themselves. These types of non-remedial land use restrictions, typically implemented by other governmental agencies, may change or be removed without DEQ approval and therefore are not approved by DEQ as part of a CAP. The presence of such non-remedial restrictions may be relevant when determining the current and likely future uses of impacted properties.

Appendix A: Default Exposure Factors

This page intentionally left blank for correct double-sided printing.

Exposure Factors

Risk assessment requires quantifying the magnitude, frequency, and duration of exposure for the receptor populations and exposure pathways selected for analysis. To determine pathway-specific intake estimates, it is necessary to select values for a number of variables in the equations used to calculate intake. The following variables were selected based on an assessment of recommendations in various guidance documents and scientific literature. When determining these values, it is often necessary to make assumptions, and in these cases, the rationale for the assumption is provided. These exposure factors are summarized in Table 1.

Averaging Time

The period over which exposure to chemicals is averaged depends on the type of toxic effect being assessed. For chronic exposure to noncarcinogenic toxicants, intakes are averaged over the period of exposure, so the averaging time is equal to the exposure duration. Intakes of carcinogens are calculated by prorating the total cumulative dose over a lifetime. The different approach is based on the idea that for carcinogens, a higher dose received over a shorter period is equivalent to a corresponding lower dose spread over a lifetime. The averaging time selected for carcinogens, 70 years, is based on the U.S. Environmental Protection Agency's (EPA) *Risk Assessment Guidance for Superfund* (EPA 1989).

Body Weight

It is appropriate to use an average value for this parameter. The default body weight for adult receptors is 70 kilograms (kg) and represents the EPA standard default exposure factor (EPA 1991a). There is evidence presented in the *Exposure Factors Handbook* (EPA 2011) that Americans are getting heavier, and currently the actual average adult body weight is 80 kg. However, the derivation of cancer slope factors assumes a body weight of 70 kg, so it is more appropriate to also use this value for average body weight. The child body weight value is 15 kg, which is the mean value for children aged 6 months to 6 years (EPA 2011). It is also a standard default value in EPA's 1991 *Risk Assessment Guidance for Superfund* (EPA 1991a).

Exposure Duration

The residential exposure duration is the EPA standard default of 30 years (EPA 1991a). This period is divided into 6 years of exposure as a child and 24 years as an adult. These time periods are used in combination with other age group–specific exposure parameters to assess exposure to carcinogenic chemicals. Noncarcinogenic chemical exposure is conservatively assessed using the child receptor and an exposure duration of 6 years. For the nonresidential adult receptor, the exposure duration is 25 years, which is an EPA standard default exposure factor (EPA 1991a) and is also used in *Risk Assessment Guidance for Superfund, Part B* (EPA 1991b). This value was a 95th-percentile value for men in the manufacturing sector, based on an analysis of U. S. Bureau of Labor Statistics data (EPA 2002). An exposure duration of 25 years is considered protective across a wide spectrum of industrial and commercial sectors (EPA 2002) and so is an appropriate default for nonresidential receptors. The exposure duration for the construction

worker is 30 days (0.08 year); this is assumed to be a conservative estimate of exposure for most construction projects.

Exposure Frequency

The exposure frequency for residential receptors is 350 days per year for all exposure routes that do not involve direct contact with soil. This exposure frequency is the EPA standard default exposure factor (EPA 1991a). The nonresidential scenario assumes an exposure frequency of 250 days per year. This value is the EPA standard default for commercial or industrial scenarios (EPA 1991a) and so was considered appropriate for all nonresidential receptors except for construction workers. For the construction worker scenario, the exposure frequency is 30 days per year.

Exposure Frequency for Direct Contact with Soil

For exposure routes involving direct contact with soil—including soil ingestion, dermal exposure, and vapor and particulate inhalation—it is assumed that receptors have contact with soil primarily in warmer months when the ground is not frozen or snow covered. For this reason, an exposure frequency of 270 days per year is used for these exposure routes for the residential scenario; 180 days per year is used for the nonresidential scenario. The direct contact exposure frequency for construction workers is 30 days per year.

Soil Ingestion Rate

The soil ingestion rate for residential child and adult receptors is 200 milligrams per day (mg/day) and 100 mg/day, respectively. These values are EPA standard default exposure factors (1991a). Although both EPA (1991a) and the *Exposure Factors Handbook* (EPA 1997) recommend a soil ingestion rate of 50 mg/day for workers other than construction workers, it was decided to use a value of 100 mg/day to adequately address the potential soil exposures encountered by all nonresidential adult receptors.

For example, a value of 50 mg/day might be appropriate for office workers, but it would not adequately address exposure of outdoor workers, for whom a value of 100 mg/day is more appropriate (EPA 2002). The construction worker soil ingestion rate is 330 mg/day. This value is based on the 95th percentile for adult soil intake rates reported in a soil ingestion mass-balance study (Stanek et al. 1997, cited in EPA 2002).

Water Ingestion Rate

The water ingestion rate for children is 1 liter per day (L/day). Currently EPA uses 1 L/day as a default drinking water ingestion rate for infants and children, and it is considered to be an appropriate upper percentile tap water ingestion rate for children less than 10 years of age (EPA 2008). The residential adult receptor ingestion rate is 2 L/day. This value is an EPA standard default exposure factor (EPA 1991a). According to EPA (1997), the intake rate of 2 L/day corresponds to the 84th percentile of the intake rate distribution among adults in a study by Ershow and Cantor (1989). EPA (1997) lists an average tap water intake for adults of 1.41 L/day. The nonresidential adult ingestion rate is 1 L/day; this value is an EPA standard default exposure factor (EPA 1991a).

Exposure Time for Outdoor Inhalation

Residential receptors are assumed to spend 2 hours outdoors at their residence. This is an EPA-recommended value (1997). Nonresidential receptors are assumed to spend 6 hours outside; this value overestimates exposure of indoor workers, but it is appropriate for outdoor workers. Construction workers are assumed to spend 10 hours per day outdoors, as construction workers often work 10-hour days. These exposure times are used in the inhalation portion of the direct contact equations used to derive screening levels and risk.

Dermal Relative Absorption Factor

The dermal relative absorption factor values are based on recommendations contained in the EPA's *Risk Assessment Guidance for Superfund, Part E, Supplemental Guidance for Dermal Risk Assessment* (EPA 2004). The EPA recommends an absorption factor of 0.13 for benzo(a)pyrene and other polynuclear aromatic hydrocarbons (PAHs) and 0 for volatile organic compounds (VOCs).

Soil-to-Skin Adherence Factor

The soil-to-skin adherence factor values are derived from recommendations from an analysis of soil adherence study data by the EPA (EPA 2004). This analysis calculated body-part-weighted adherence factor values using studies involving upper-end activities for soil-skin adherence and median values of body surface area. The recommended adult residential value, based on a central-tendency-weighted adherence factor of a high-end soil contact activity (e.g., gardening), is consistent with a reasonable maximum exposure (RME) for contact rates in a variety of activities. The same approach of using the high end of a mean is used for the recommended child value, which is the 50th percentile weighted adherence factor for children playing in wet soil. Similarly, the commercial/industrial worker recommended adherence factor is based on the 50th percentile weighted adherence factor for utility workers, a high-end contact activity. For the construction worker, a 95th percentile weighted adherence factor is used to represent RME.

Skin Surface Area for Dermal Contact with Soil

Skin surface areas for dermal soil contact are based on residential and industrial RME recommended values contained in EPA's *Risk Assessment Guidance for Superfund, Part E, Supplemental Guidance for Dermal Risk Assessment* (EPA 2004).

Table 1. Default Exposure Factors

Exposure Parameter	Symbol	Units	Default Value	Reference
Averaging Time (AT)				
Averaging Time—Carcinogen	ATc	years	70	EPA 1989 (p. 6-23)
Averaging Time—Noncarcinogen	ATnc	years	Equivalent to exposure duration	EPA 1989 (p. 6-23)
Body Weight (BW)				
Child	BWc	kg	15	EPA 1991a (p. 15)
Adult	BWa	kg	70	EPA 1991a (p. 15)
Exposure Duration (ED)				
Resident (child)	EDc	years	6	EPA 1991a (p. 15)
Resident (adult)	EDa	years	24	EPA 1991a (p. 15)
Nonresidential Worker	ED	years	25	EPA 1991a (p. 15)
Construction Worker	ED	years	1	EPA 2002 (Exhibit 5-1)
Exposure Frequency (EF)				
Resident	EFr	days/yr	350	EPA,1991a (p.15)
Nonresidential Worker	EF	days/yr	250	EPA 1991a (p.15)
Construction Worker	EF	days/yr	30	Professional judgment
Exposure Frequency for Direct Contact Pathways (EF)				
Resident	EFres	days/yr	270	Professional judgment
Nonresidential Worker	EFd	days/yr	180	Professional judgment
Construction Worker	EFd	days/yr	30	Professional judgment
Soil Ingestion Rate (IR)				
Resident (child)	IRs-c	mg/day	200	EPA 1991a (p. 15)
Resident (adult)	IRs-a	mg/day	100	EPA 1991a (p. 15)
Nonresidential Worker	IRs	mg/day	100	EPA 2002 (Exhibit 1-2)
Construction Worker	IRs	mg/day	330	EPA 2002 (Exhibit 1-2)
Daily Water Ingestion Rate (IRw)				
Resident (child)	IRw-c	L/day	1	EPA 2008
Resident (adult)	IRw-a	L/day	2	EPA 1991a (p. 15)
Nonresidential Worker	IRw	L/day	1	EPA 1991a (p. 15)
Exposure Time for Inhalation (ET)				
Resident (child)	ETo-c	hr/day	Outdoor: 2 Indoor: 24	EPA 1997 (p. 15-17)

Exposure Parameter	Symbol	Units	Default Value	Reference
Resident (adult)	ETo-a	hr/day	Outdoor: 2 Indoor: 24	EPA 1997 (p. 15-17)
Nonresidential Worker	ETo	hr/day	Outdoor: 6 Indoor: 8	Professional judgment
Construction Worker (outdoor only)	ETo	hr/day	10	Professional judgment
Oral Relative Absorption Factor (RAF)				
Oral Relative Absorption Factor	RAFo	—	Assume 100%	EPA 2004 (p. 4-2)
Dermal Relative Absorption Factor (RAFd)				
Volatile organic compounds	RAFd	—	0	EPA 2004 (pg. 3-18)
Benzo(a)pyrene and other polynuclear aromatic hydrocarbons	RAFd	—	0.13	EPA 2004 (Exhibit 3-4)
Soil-to-Skin Adherence Factor (M)				
Residential (child)	Mc	mg/cm^2	0.2	EPA 2004 (p.3-14)
Residential (adult)	Ma	mg/cm2	0.07	EPA 2004 (p. 3-14)
Nonresidential Worker	M	mg/cm^2	0.2	EPA 2004 (p. 3-17)
Construction Worker	M	mg/cm^2	0.3	EPA 2004 (Exhibit 3-3)
Skin Surface Area for Dermal Contact with Soil (SA)				
Child Receptors	SAc	cm^2/day	2800	EPA 2004 (Exhibit 3-5)
Adult Receptors	SAa	cm^2/day	5700	EPA 2004 (Exhibit 3-5)
Nonresidential Worker Receptors	SA	cm^2/day	3300	EPA 2004 (Exhibit 3-5)
Construction Worker Receptors	SA	cm^2/day	3300	EPA 2004 (Exhibit 3-5)

Note: Exposure factors for the age-adjusted resident are calculated from the values listed for child and adult receptors using the equations in Appendix E.

Exposure to Mutagenic Carcinogens

Exposure to these chemicals carries greater risk when it occurs early in life. Therefore, the age at which exposure occurs must be considered for residential receptors. For these receptors, the 30-year exposure duration is divided into four periods: exposures occurring between the ages of 0–2 years, 2–6 years, 6–16 years, and 16–30 years (EPA 2005).

Different multipliers are incorporated for these time periods so that early-life exposure is weighted more heavily. The 0–2 year and 2–6 year exposure periods use the child-specific values for several exposure parameters: body weight, soil ingestion rate, soil-to-skin adherence factor, and skin surface area for dermal contact. The corresponding adult-specific values are used for the 6–16 year and 16–30 year exposure periods.

Appendix B: Default Fate and Transport Parameter Values

This page intentionally left blank for correct double-sided printing.

Introduction

Several routes of exposure evaluated in the *Idaho Risk Evaluation Manual for Petroleum Releases* (REM) involve pathways where chemicals transfer across media. These pathways include inhalation of vapors originating from the volatilization of chemicals of interest (COI) from petroleum-impacted soil or ground water in indoor air, ingestion of ground water containing chemicals leached from soil, and inhalation of volatiles and particulates from surficial soil. Models are used to simulate these cross-media transfer processes, estimate exposure point concentrations, and calculate target levels. This appendix describes the models and selection criteria for the default fate and transport parameter values used to develop the Idaho default screening levels and to some degree the remedial action target levels. A summary of the parameters and sources used to develop them is provided in Table 1 at the end of this appendix.

Soil Properties

Unsaturated Zone

Generic unsaturated zone soil properties were based on an assumed sandy loam soil textural class. Nielson and Rogers (1990) and Hers (2002) present data on average soil physical and hydraulic properties for 12 Natural Resources Conservation Service soil textural classes. Data obtained from these compilations include mean particle diameter, total porosity, saturated moisture content, residual moisture content, van Genuchten parameters describing the shape of the moisture characteristic curve, and saturated hydraulic conductivity. Bulk density was calculated from total porosity. Soil vapor permeability was calculated using van Genuchten equations described in the U.S. Environmental Protection Agency's (EPA) *User's Guide for Evaluating Subsurface Vapor Intrusion into Buildings* (EPA 2003), the hydraulic properties of the sandy loam soil noted above, and average moisture content conditions. Derivation of the average moisture contents is described below.

Infiltration rates for high- and low-precipitation areas of Idaho were developed, and the value for high-precipitation areas is used as the Idaho default target level value. The high-precipitation area annual infiltration rate of 25 centimeters is based on field studies and water balance calculations done in northern Idaho on the Rathdrum Prairie (Hammel et al. 1995). This value represents about 40% of the total annual precipitation. The annual infiltration rate for low-precipitation areas (1.4 centimeters) is based on investigations by Cecil et al. (1992). This latter work was conducted in areas of native vegetation at the Idaho National Laboratory in eastern Idaho. Using stable isotopes and other tracers, a long-term estimate of 1 centimeter per year infiltration was calculated.

This infiltration rate represents approximately 5% of total annual precipitation. This percentage was applied to the total annual precipitation in Boise (11.7 inches/year), with the assumption that Boise conditions represent average low-precipitation conditions.

Average soil moisture content values for low- and high-precipitation conditions were derived by simulating infiltration into a homogeneous soil profile with the sandy loam hydraulic properties discussed above. The variably saturated flow and transport code HYDRUS-1D (Kool and van Genuchten 1991) was used to conduct the simulations. The simulations were run until steady-state conditions were achieved, and the moisture content at that time was noted. These values (0.17 cm^3/cm^3, low precipitation, and 0.20 cm^3/cm^3, high precipitation) are consistent with field capacity (0.33 bar) moisture content values for sandy loam texture class soils presented by Rawls et al. (1982).

The moisture content in the capillary fringe and the capillary fringe thickness were derived using methods and equations described in the EPA *User's Guide for Evaluating Subsurface Vapor Intrusion into Buildings* (2003). The mean particle diameter of 0.03 centimeters used in these calculations is typical of a sandy loam soil type.

The default value for fractional organic carbon content in the vadose zone (0.001) was selected from the statistical analysis of national soil survey data by Carsel et al. (1988). It represents the median value for subsoils with sandy loam textures.

Saturated Zone

The default scenario selected to represent the saturated zone is a sandy, alluvial aquifer of moderate hydraulic conductivity. Selected saturated zone properties and ground water mixing zone thickness were taken from those developed for the soils protective of ground water pathway in Appendix A of the *Risk Based Corrective Action Guidance Document for Petroleum Releases* (DEQ 1996). Total porosity, bulk density, and fraction organic carbon are similar to that of the unsaturated zone soil.

Enclosed Space Parameters

The enclosed space parameters are used in combination with soil and ground water properties to define the conditions controlling the volatilization of COI vapors from petroleum-impacted soil, ground water, and soil vapor into indoor spaces and to predict exposure point concentrations of chemicals in indoor air. Scenarios were developed for residential and nonresidential settings. Both the residential and nonresidential scenarios selected consist of one-story, slab-on-grade structures lying directly over the source of contamination. For structures with finished basements, reasonable values for basement depth below grade of 200 cm and height of enclosed space of 366 cm (EPA 2003) can be assumed. Structures with crawl spaces are not as readily characterized because of the common occurrence of earthen floors and variable size and ventilation. The primary differences between the two scenarios are the size of the structure and the number of air exchanges per time period. The nonresidential structure is larger and exchanges more air than the residential structure.

The size of structure for each scenario was based on residential and commercial building survey data collected by the U.S. Department of Energy (DOE 1995, 2001). Data from the western census region of the 1993 housing survey (DOE 1995) were used to further describe residential structures. In this region, 33% of all homes had heated floor space square footage between 1,000

and 1,599 square feet, constituting the largest proportion of all size classes. Approximately 50% of all homes were one-story, single-family homes. The next largest category was multistory apartment buildings, accounting for 29% of all residential structures. Homes with concrete slabs or crawl spaces each constituted about 33% of all homes, while 15% had basements. A sensitivity analysis evaluating the impact of concrete slabs versus crawl spaces on target levels showed little difference.

For nonresidential structures, data from the mountain division of the western region of the 1999 Commercial Building Energy Consumption Survey was used (DOE 2001). The median square footage per commercial building in this area was 5,000 square feet, and 66% of all buildings in this area were one story. A slab-on-grade foundation and indoor building height of 8 feet were assumed. These values can be modified during the development of a site-specific evaluation to accommodate actual structure conditions.

The default value chosen for air exchange rates in commercial buildings is based on expected values for buildings built to meet ventilation standards of the American Society of Heating, Refrigeration, and Air Conditioning Engineers (ASHRAE 2004). The default value for residential structures is based on an analysis by the Michigan Department of Environmental Quality (MDEQ 1998). Values for other structural parameters—specifically the dimensions of foundation cracks, wall/foundation thickness, and pressure differentials between the space and the outdoors—are based on data presented in the *User's Guide for Evaluating Subsurface Vapor Intrusion into Buildings* (EPA 2003).

In the Johnson-Ettinger model equations, there is a dependent relationship between the width of foundation cracks (equivalent crack radius) and the fraction of the total floor space below grade occupied by cracks. It was decided to fix the equivalent crack width at 0.1 centimeters and allow the fraction of cracks to vary, with a minimum value of 0.0005 specified, during the calculation of the total area of cracks in the default structure. This minimum value is what is suggested as a reasonable lower end of the range for this parameter by Johnson (2005).

Source characteristics for calculation of indoor air pathways assumed a 1-foot separation distance between the top of the soil or ground water source and the building foundation. This distance is the minimum that can be considered by the model and was considered extremely conservative with respect to maximizing vapor migration into a structure.

For ground water sources, this soil separation distance includes the capillary fringe thickness of 25 centimeters. In making finite mass calculations, the soil source was assumed to be 5 feet (153 centimeters) thick.

Particulate Emission Factor Parameters

All parameter values used in the calculation of the particulate emission factor are taken directly from the EPA's *Soil Screening Guidance* (EPA 1996). Idaho-specific values for the Q/C dispersion factor for a 0.5-acre size source and the average wind speed for Boise were selected as default values.

Models

The default models selected to estimate the transport of chemicals between various media and within select media, such as ground water, include the following:

- The Johnson-Ettinger model (Johnson and Ettinger 1991) for transport of volatile chemicals between soil, soil vapor, or ground water and indoor air—Implementation of the model includes the effects of advection near the building and diffusion to the building from the source and infinite and finite source masses. This model does not incorporate biodegradation of chemicals during transport from the source into the indoor air.
- The dilution attenuation factor model for the soil to ground water pathway implemented in the EPA *Soil Screening Guidance* (EPA 1996)—Soil leachate generated using the high infiltration rate is mixed with ground water having the Darcy velocity described above. Target levels are estimated in ground water directly below the source.
- The Domenico model for transport of chemicals in the saturated zone—This is a steady-state model that includes advection, sorption, three-dimensional dispersion, and decay (Domenico 1990). Equations for calculating dispersivity values for use in the ground water transport model are those derived by Xu and Eckstein (1995).
- The Cowherd equation for transport and dispersion of particulates as described in the EPA *Soil Screening Guidance* (EPA 1996).

Table 1. Default fate and transport parameter values

Parameter	Symbol	Units[a]	Default Value	Reference
Soil Parameters				
Unsaturated Zone Soil				
Source-building separation	LTs	cm	30	Professional judgment, see discussion
Source bottom-building separation	LTSB	cm	183	Professional judgment, see discussion

Appendix D: Default Toxicity Values

This page intentionally left blank for correct double-sided printing.

The table below provides a list of the default carcinogenic and noncarcinogenic toxicity factors and oral and dermal relative absorption factors used in the risk evaluation process. All toxicity factor values, oral relative absorption factors, and dermal relative absorption factors for polynuclear aromatic hydrocarbons were obtained from the U.S. Environmental Protection Agency (EPA) regional screening level website and are current as of May 2018:

http://www.epa.gov/reg3hwmd/risk/human/rb-concentration_table/Generic_Tables/index.htm

In their *Risk Assessment Guidance for Superfund, Volume I: Human Health Evaluation Manual* (Part E, Supplemental Guidance for Dermal Risk Assessment), the EPA did not provide dermal relative absorption factors for volatile organic compounds based on the rationale that these compounds would tend to be volatilized from the soil on skin. Based on this rationale, the dermal relative absorption factors for volatile organic compounds is assumed to be zero.

Chemicals	CAS Number	Oral Slope Factor (kg-day/mg)[a]	Unit Inhalation Risk ($\mu g/m^3$)[b]	Oral Reference Dose (mg/kg-day)[c]	Inhalation Reference Concentration (mg/m^3)[d]	Oral Relative Absorption Factor	Dermal Relative Absorption Factor

1 Target Levels for Non-Residential and Construction Worker Exposures

1.1 Indoor Inhalation of Vapor Emissions

Carcinogenic effects

$$RBTL_{ai} = \frac{TR \times AT_c \times 365}{ED \times EF \times ET_i \times IUR \times 1000}$$

Noncarcinogenic effects

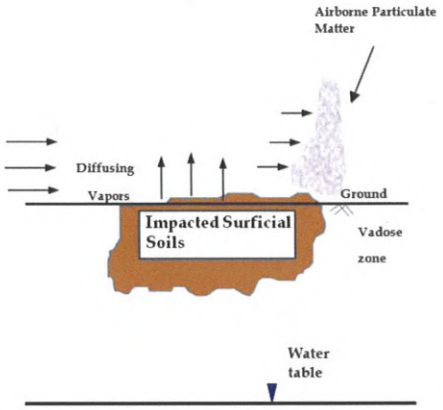
$$RBTL_{ai} = \frac{THQ \times AT_{nc} \times 365}{ED \times EF \times ET_i \times \left(\frac{1}{RfC}\right)}$$

Source: EPA 2009, modified from equations 6 and 11

Where:

$RBTL_{ai}$	=	Risk-based target level for indoor air inhalation [mg/m^3]
TR	=	Target risk or the increased chance of developing cancer over a lifetime due to exposure to a chemical [-]
THQ	=	Target hazard quotient for individual constituents [-]
AT_c	=	Averaging time for carcinogens [years]
AT_{nc}	=	Averaging time for noncarcinogens [years]
ED	=	Exposure duration [years]
EF	=	Exposure frequency [days/year]
ET_i	=	Exposure time for indoor inhalation [hours/day]
RfC	=	Chemical-specific inhalation reference concentration [mg/m^3]
IUR	=	Chemical-specific inhalation unit risk [(µg/m^3)$^{-1}$]
365	=	Conversion factor [days/year]

1.2 Outdoor Inhalation of Vapors and Particulates from Surficial Soil



Carcinogenic effects

$$RBTL_{SS} = \frac{TR \times AT_c \times 365}{ED \times EF_d \times ET \times IUR \times \left(\frac{1}{VF} + \frac{1}{PEF}\right) \times 1000}$$

Noncarcinogenic effects

$$RBTL_{SS} = \frac{THQ \times AT_{nc} \times 365}{ED \times EF_d \times ET \times \left(\frac{1}{RfC}\right) \times \left(\frac{1}{VF} + \frac{1}{PEF}\right)}$$

Source: EPA 2011

Where:

$RBTL_{SS}$	=	Risk-based target level for outdoor inhalation of vapors and particulates from surficial soil [mg/kg dry weight]
TR	=	Target risk or the increased chance of developing cancer over a lifetime due to exposure to a chemical [-]
THQ	=	Target hazard quotient for individual constituents [-]
VF	=	Surficial soil to ambient air volatilization factor [$(m^3$-air)/(kg-soil)]
PEF	=	Particulate emission factor [$(m^3$-air)/(kg-soil)]
AT_c	=	Averaging time for carcinogens [years]
AT_{nc}	=	Averaging time for noncarcinogens [years]
ED	=	Exposure duration [years]
EF_d	=	Exposure frequency for direct contact pathway [days/year]
ET	=	Exposure time [hours/day]
RfC	=	Chemical-specific inhalation reference concentration [mg/m^3]
IUR	=	Chemical-specific inhalation unit risk [$(\mu g/m^3)^{-1}$]
365	=	Conversion factor [days/year]

1.3 Direct Ingestion of Surficial Soil

Carcinogenic effects

$$RBTL_S = \frac{TR \times BW \times AT_c \times 365}{SF_o \times EF_d \times ED \times IR_s \times RAF_o \times 10^{-6}}$$

Noncarcinogenic effects

$$RBTL_S = \frac{THQ \times BW \times AT_{nc} \times 365}{EF_d \times ED \times \left(\frac{1}{RAF_o \times RfD_o}\right) IR_s \times 10^{-6}}$$

Source: EPA 1996, p. 19

Where:

$RBTLs$	=	Risk-based target level for the ingestion of soil [mg/kg-wet soil]
TR	=	Target risk or the increased chance of developing cancer over a lifetime due to exposure to a chemical [-]
THQ	=	Target hazard quotient for individual constituents [-]
BW	=	Body weight [kg]
AT_c	=	Averaging time for carcinogens [years]
AT_{nc}	=	Averaging time for noncarcinogens [years]
ED	=	Exposure duration [years]
EF_d	=	Exposure frequency [days/year]
IR_s	=	Soil ingestion rate [mg/day]
RAF_o	=	Oral relative absorption factor [-]
RfD_o	=	Chemical-specific oral reference dose [mg/(kg-day)]
SF_o	=	Chemical-specific oral cancer slope or potency factor [mg/(kg-day)]$^{-1}$
365	=	Conversion factor [days/year]
10^{-6}	=	Conversion factor [kg/mg]

1.4 Dermal Contact with Surficial Soil

Carcinogenic effects

$$RBTL_{DC} = \frac{TR \times BW \times AT_c \times 365}{SF_o \times SA \times M \times RAF_d \times ED \times EF_d \times 10^{-6}}$$

Noncarcinogenic effects

$$RBTL_{DC} = \frac{THQ \times BW \times AT_{nc} \times 365}{SA \times M \times \left(\frac{1}{RfD_o \times RAF_d}\right) \times ED \times EF_d \times 10^{-6}}$$

Source: Modified from EPA 1989, p. 6-41; See also EPA 2007, Appendix D, p. D-6

Where:

$RBTL_{DC}$	=	Risk-based target level for dermal contact with soil [mg/kg-wet soil]
TR	=	Target risk or the increased chance of developing cancer over a lifetime due to exposure to a chemical [-]
THQ	=	Target hazard quotient for individual constituents [-]
BW	=	Body weight [kg]
AT_c	=	Averaging time for carcinogens [years]
AT_{nc}	=	Averaging time for noncarcinogens [years]
ED	=	Exposure duration [years]
EF_d	=	Exposure frequency for direct contact pathway [days/year]
RAF_d	=	Dermal relative absorption factor [-]
SA	=	Skin surface area [cm^2/day]
M	=	Soil to skin adherence factor [mg/cm^2]
RfD_o	=	Chemical-specific oral reference dose [mg/(kg-day)]
SF_o	=	Chemical-specific oral cancer slope or potency factor $[mg/(kg\text{-}day)]^{-1}$
365	=	Conversion factor [days/year]
10^{-6}	=	Conversion factor [kg/mg]

1.5 Combined Direct Contact Soil Pathway: Ingestion, Inhalation of Vapors and Particulates, and Dermal Contact

Carcinogenic effects

$$RBTL_{ss-combined} = \frac{TR \times BW \times AT_c \times 365}{ED \times EF_d \times SF_o \times 10^{-6}\left[\left(IR_s \times RAF_o\right) + \left(SA \times M \times RAF_d\right)\right]} + \frac{TR \times AT_c \times 365}{ED \times EF_d \times ET \times IUR \times \left(\frac{1}{VF} + \frac{1}{PEF}\right) \times 1000}$$

Noncarcinogenic effects

$$RBTL_{ss-combined} = \frac{THQ \times BW \times AT_{nc} \times 365}{ED \times EF_d \times 10^{-6} \times \frac{1}{RfD_o}\left[\left(IR_s \times RAF_o\right) + \left(SA \times M \times RAF_d\right)\right]} + \frac{THQ \times AT_{nc} \times 365}{ED \times EF_d \times ET \times \frac{1}{RfC}\left(\frac{1}{VF} + \frac{1}{PEF}\right)}$$

Note: All parameters are defined under the individual pathway equations above (sections 1.2–1.4).

1.6 Subsurface Soil Concentrations Protective of Indoor Vapor Inhalation

$$RBTL_{si} = \frac{RBTL_{ai}}{\alpha} * EF$$

Where:

$RBTL_{si}$ = Risk-based target level for indoor inhalation of vapors from subsurface soils [mg/kg-dry soil]

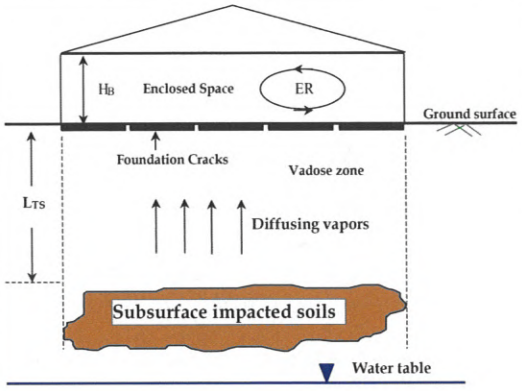
$RBTL_{ai}$ = Risk-based target level for indoor inhalation of air [mg/m^3-air]

α = Chemical-specific attenuation factor from subsurface soil to indoor (enclosed space) air derived from the Johnson-Ettinger model [-]

EF = Equilibrium factor to convert vapor target level to total soil target level

$$= \frac{\theta_{ws} + (K_D \rho_s) + (H \theta_{as})}{(H \rho_s)} * 0.001$$

Where:



ρ_s = Dry soil bulk density [g-soil/cm^3-soil]

H = Chemical-specific Henry's Law constant [(L-H_2O)/(L-air)]

θ_{as} = Volumetric air content in the vadose zone soils [cm^3-air/cm^3-soil]

θ_{ws} = Volumetric water content in vadose zone soils [cm^3-H_2O/cm^3- soil]

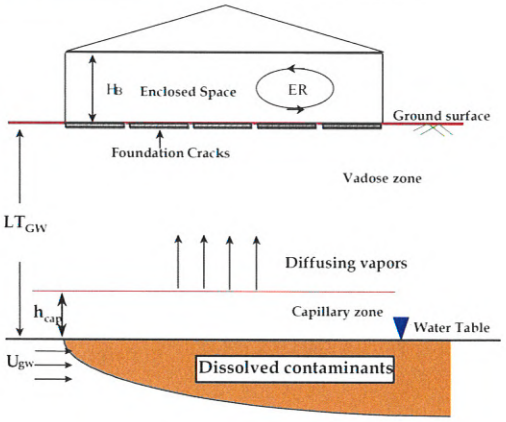
K_D = $f_{oc} \times K_{oc}$ = Chemical-specific soil-water sorption coefficient [cm^3-H_2O/g-soil]

1.7 Ground Water Concentrations Protective of Indoor Vapor Inhalation

$$RBTL_{wi} = \frac{RBTL_{ai}}{\alpha} * EF$$

Where:

$RBTL_{wi}$ = Risk-based target level for indoor inhalation of vapors from ground water [mg/L-H_2O]



$RBTL_{ai}$ = Risk-based target level for indoor inhalation of air (mg/m^3-air)

α = Chemical-specific attenuation factor from ground water to indoor (enclosed space) air derived from the Johnson-Ettinger model [-]

EF = Equilibrium factor to convert vapor target level to water target level
= (1/H)*0.001m^3/L

Where:

H = Henry's Law Constant [-]

1.8 Direct Ingestion of Ground Water

Carcinogenic effects

$$RBTL_w = \frac{TR \times BW \times AT_c \times 365}{IR_w \times ED \times EF \times SF_o}$$

Noncarcinogenic effects

$$RBTL_w = \frac{THQ \times BW \times AT_{nc} \times 365}{IR_w \times \left(\frac{1}{RfD_o}\right) \times ED \times EF}$$

Source: Modified from EPA 1989, p. 6-35

Where:

$RBTL_w$	=	Risk-based target level for ingestion of ground water [mg/L-H_2O]
TR	=	Target risk or the increased chance of developing cancer over a lifetime due to exposure to a chemical [-]
THQ	=	Target hazard quotient for individual constituents [-]
BW	=	Body weight [kg]
AT_c	=	Averaging time for carcinogens [years]
AT_{nc}	=	Averaging time for noncarcinogens [years]
IR_w	=	Water ingestion rate [L/day]
ED	=	Exposure duration [years]
EF	=	Exposure frequency [days/year]
RfD_o	=	Chemical-specific oral reference dose [mg/(kg-day)]
SF_o	=	Chemical-specific oral cancer slope or potency factor $[mg/(kg\text{-}day)]^{-1}$
365	=	Conversion factor [days/year]

1.9 Johnson and Ettinger Infinite Source Model

The model predicts the vapor concentration inside a building from the measured soil-vapor, soil, or ground water concentration.

$$C_{building} = \alpha \times C_{source}$$

Where:

$$C_{source} = \frac{H \times C_{soil} \times \rho_s}{\theta_{ws} + K_d \times \rho_s + H \times \theta_{as}}$$

OR

$$C_{source} = H \times C_w$$

OR

C_{source} = Measured soil-vapor concentration [mg/L]

$$\alpha = \frac{\frac{D_T^{eff} A_B}{Q_{building} L_T} \times EXP\left(\frac{Q_{soil} L_{crack}}{D_{crack}^{eff} A_{crack}}\right)}{EXP\left(\frac{Q_{soil} L_{crack}}{D_{crack}^{eff} A_{crack}}\right) + \frac{D_T^{eff} A_B}{Q_{building} L_T} + \frac{D_T^{eff} A_B}{Q_{soil} L_T} \times \left[EXP\left(\frac{Q_{soil} L_{crack}}{D_{crack}^{eff} A_{crack}}\right) - 1\right]}$$

Source: EPA 2003

$C_{building}$	=	Steady-state vapor-phase concentration in the building [mg/L]
α	=	Attenuation coefficient in the vapor phase [-]
C_{source}	=	Vapor-phase concentration at the source [mg/L]
C_{soil}	=	Concentration in soil [mg/kg]
C_w	=	Concentration in ground water [mg/L]
H	=	Chemical-specific Henry's Law constant [(L-H_2O)/(L-air)]
ρ_s	=	Dry soil bulk density [g-soil/cm^3-soil]
θ_{ws}	=	Volumetric water content in vadose zone soils [cm^3-H_2O/cm^3-soil]
K_d	=	$f_{oc} \times K_{oc}$
	=	Chemical-specific soil-water sorption coefficient [cm^3-H_2O/g-soil]
θ_{as}	=	Volumetric air content in vadose zone soils [cm^3-air/cm^3-soil]
D_T^{eff}	=	Total overall effective diffusion coefficient [cm^2/s]
D_{crack}^{eff}	=	Effective diffusion coefficient through cracks [cm^2/s]
A_B	=	Area of the enclosed space below grade [cm^2]
$Q_{building}$	=	Building ventilation rate [cm^3/s]
L_T	=	Source-building separation [cm]
Q_{soil}	=	Volumetric flow rate of soil gas into the enclosed space [cm^3/s]
L_{crack}	=	Enclosed space foundation or slab thickness [cm]
A_{crack}	=	Total area of cracks [cm^2]

1.9 Johnson and Ettinger Infinite Source Model (continued)

Where:

$$Q_{building} = L_B W_B H_B ER$$

$$Q_{soil} = \frac{2\pi \Delta P k_v X_{crack}}{\mu \ln\left(\frac{2Z_{crack}}{r_{crack}}\right)}$$

For vapor release from soil:

$$D_T^{eff} = \frac{L_T}{\sum_{i=0}^{n} \frac{L_i}{D_i^{eff}}}$$

For vapor release from ground water:

$$D_T^{eff} = D_s^{eff} \qquad D_{crack}^{eff} = D_s^{eff}$$

$$D_T^{eff} = D_{ws}^{eff} = \frac{L_T}{\frac{h_{cap}}{D_{cap}^{eff}} + \frac{(L_T - h_{cap})}{D_s^{eff}}} \qquad h_{cap} = \frac{0.75}{D}$$

$Q_{building}$	=	Building ventilation rate [cm^3/s]
L_B	=	Length of building [cm]
W_B	=	Width of building [cm]
H_B	=	Height of building [cm]
ER	=	Air exchange rate [1/s]
Q_{soil}	=	Volumetric flow rate of soil gas into the enclosed space [cm^3/s]
π	=	3.14159
ΔP	=	Pressure differential between the soil surface and the enclosed space [$g/cm\text{-}s^2$]
k_v	=	Soil vapor permeability [cm^2]
X_{crack}	=	Floor-wall seam perimeter [cm]
μ	=	Viscosity of air [g/cm-s]
Z_{crack}	=	Crack depth below grade [cm]
r_{crack}	=	Equivalent crack radius [cm]
D_T^{eff}	=	Total overall effective diffusion coefficient [cm^2/s]
L_T	=	Source-building separation [cm]
L_i	=	Thickness of soil layer *i* [cm]
D_i^{eff}	=	Effective diffusion coefficient in soil layer *i* [cm^2/s]
n	=	Number of soil layers [-]
D_s^{eff}	=	Effective diffusion coefficient in soil [cm^2/s]
D_{ws}^{eff}	=	Effective diffusion coefficient in capillary fringe [cm^2/s]
h_{cap}	=	Thickness of capillary fringe zone [cm]
D_{cap}^{eff}	=	Effective diffusion coefficient in the capillary fringe soil [cm^2/s]
D_{crack}^{eff}	=	Effective diffusion coefficient in the foundation/wall cracks [cm^2/s]
D	=	Mean particle diameter [cm]

1.10 Johnson and Ettinger Finite Source Model

The model predicts the vapor concentration inside a building from the measured soil concentration when the thickness of soil contamination is known.

$$C_{building} = \alpha \times C_{source}$$

Where:

$$C_{source} = \frac{H \times C_{soil} \times \rho_s}{\theta_{ws} + K_d \times \rho_s + H \times \theta_{as}}$$

$$\alpha = \frac{\rho_s \; C_{soil} \; \Delta H_c \; A_B}{Q_{building} \; C_{source} \; \tau} \left(\frac{L_T^0}{\Delta H_c} \right) \left[\left(\beta^2 + 2 \; \psi \; \tau \right)^{1/2} - \beta \right]$$

$$\beta = \left(\frac{D_T^{eff} \; A_B}{L_T^0 \; Q_{soil}} \right) \left[1 - \exp\left(- \frac{Q_{soil} \; L_{crack}}{D_{crack}^{eff} \; A_{crack}} \right) \right] + 1$$

$$\psi = \frac{D_T^{eff} \; C_{source}}{\left(L_T^0 \right)^2 \; \rho_s \; C_{soil}}$$

$$\tau_D = \frac{\left[\Delta H_c / L_T^0 + \beta \right]^2 - \beta^2}{2 \; \psi}$$

Source: EPA 2003

$C_{building}$	=	Steady-state vapor-phase concentration in the building [mg/L]
α	=	Attenuation coefficient in the vapor phase [-]
C_{source}	=	Vapor-phase concentration at the source [mg/L]
C_{soil}	=	Original concentration in soil [mg/kg]
H	=	Chemical-specific Henry's Law constant [(L-H_2O)/(L-air)]
ρ_s	=	Dry soil bulk density [g-soil/cm^3-soil]
θ_{ws}	=	Volumetric water content in vadose zone soils [cm^3-H_2O/cm^3-soil]
K_d	=	$f_{oc} \times K_{oc}$
	=	Chemical-specific soil-water sorption coefficient [cm^3-H_2O/g-soil]
θ_{as}	=	Volumetric air content in vadose zone soils [cm^3-air/cm^3-soil]
ΔH_c	=	Initial thickness of contamination [cm]
τ_D	=	Time for source depletion [seconds]
τ	=	Exposure interval [seconds]
D_T^{eff}	=	Total overall effective diffusion coefficient [cm^2/s]
D_{crack}^{eff}	=	Effective diffusion coefficient through cracks [cm^2/s]
A_B	=	Area of the enclosed space below grade [cm^2]
$Q_{building}$	=	Building ventilation rate [cm^3/s]
L_T^0	=	Source-building separation at time = 0 [cm]
Q_{soil}	=	Volumetric flow rate of soil gas into the enclosed space [cm^3/s]
A_{crack}	=	Total area of cracks [cm^2]
L_{crack}	=	Enclosed space foundation or slab thickness [cm]

2 Target Levels for Residential Exposures

2.1 Indoor Inhalation of Vapor Emissions

Carcinogenic effects

$$RBTL_{ai\text{-}res} = \frac{TR \times AT_c \times 365}{EF_r \times ED_r \times ET_{ra} \times IUR}$$

Noncarcinogenic effects

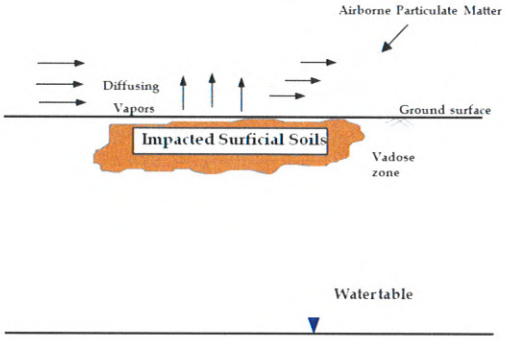
$$RBTL_{ai\text{-}res} = \frac{THQ \times AT_{nc} \times 365}{EF_r \times ED_r \times ET_{ra} \times \left(\frac{1}{RfC}\right)}$$

Source: EPA 2009, modified from equations 6 and 11

Where:

$RBTL_{ai\text{-}res}$	=	Residential risk-based target level in indoor air [mg/m^3]
TR	=	Target risk or the increased chance of developing cancer over a lifetime due to exposure to a chemical [-]
THQ	=	Target hazard quotient for individual constituents [-]
AT_c	=	Averaging time for carcinogens [years]
AT_{nc}	=	Averaging time for noncarcinogens [years]
ED_r	=	Exposure duration for resident [years]
EF_r	=	Residential exposure frequency [days/year]
ET_{ra}	=	Indoor residential exposure time [hours/day]
RfC	=	Chemical-specific inhalation reference concentration [mg/m^3]
IUR	=	Chemical-specific inhalation unit risk [µg/m^3]$^{-1}$
365	=	Conversion factor [days/year]

2.2 Outdoor Inhalation of Vapors and Particulates from Surficial Soil



Carcinogenic effects

$$RBTL_{SS} = \frac{TR \times AT_c \times 365}{ED_r \times EF_{res} \times ET_{o-r} \times IUR \times \left(\frac{1}{VF} + \frac{1}{PEF}\right) \times 1000}$$

Noncarcinogenic effects

$$RBTL_{SS} = \frac{THQ \times AT_{nc} \times 365}{ED_c \times EF_{res} \times ET_{o-r} \times \left(\frac{1}{RfC}\right) \times \left(\frac{1}{VF} + \frac{1}{PEF}\right)}$$

Source: EPA 1996

Where:

$RBTL_{SS}$	=	Risk-based target level in surficial soil [mg/kg]
TR	=	Target risk or the increased chance of developing cancer over a lifetime due to exposure to a chemical [-]
THQ	=	Target hazard quotient for individual constituents [-]
VF	=	Surficial soil to ambient air volatilization factor [(m^3-air)/(kg-soil)]
PEF	=	Particulate emission factor [(m^3-air)/(kg-soil)]
AT_c	=	Averaging time for carcinogens [years]
AT_{nc}	=	Averaging time for noncarcinogens [years]
ED_c	=	Exposure duration for child [years]
ED_r	=	Residential exposure duration [years]
EF_{res}	=	Residential exposure frequency for direct contact pathway [days/year]
ET_{o-r}	=	Residential outdoor exposure time [hours/day]
RfC	=	Chemical-specific reference concentration [mg/(m^3)]
IUR	=	Chemical-specific inhalation unit risk [$\mu g/m^3]^{-1}$
365	=	Conversion factor [days/year]

2.3 Direct Ingestion of Surficial Soil

Carcinogenic effects

$$RBTLs_{-adj} = \frac{TR \times AT_c \times 365}{SF_o \times IR_{s-aa} \times RAF_o \times 10^{-6} \times EF_{res}}$$

Where:

$$IR_{s-aa} = \frac{ED_c \times IR_{s-c}}{BW_c} + \frac{(ED_{res} - ED_c) \times IR_{s-a}}{BW_a}$$

Noncarcinogenic effects

$$RBTLs = \frac{THQ \times AT_{nc} \times 365 \times BW_c}{IR_{s-c} \times \left(\frac{1}{RfD_o}\right) \times 10^{-6} \times EF_{res} \times ED_c}$$

Source: EPA 1996, p. 20

Where:

$RBTL_{s-adj}$	=	Age-adjusted risk-based target level for ingestion of soil for carcinogenic effects [mg/kg soil]
$RBTLs$	=	Risk-based target level for ingestion of soil for noncarcinogenic effects [mg/kg-soil]
TR	=	Target risk or the increased chance of developing cancer over a lifetime due to exposure to a chemical [-]
THQ	=	Target hazard quotient for individual constituents [-]
AT_c	=	Averaging time for carcinogens [years]
AT_{nc}	=	Averaging time for noncarcinogens [years]
RAF_o	=	Oral relative absorption factor [-]
RfD_o	=	Chemical-specific oral reference dose [mg/(kg-day)]
SF_o	=	Chemical-specific oral cancer slope or potency factor $[mg/(kg\text{-}day)]^{-1}$
IR_{s-aa}	=	Age-adjusted soil ingestion rate [mg-yr/kg-day]
IR_{s-c}	=	Resident child soil ingestion rate [mg/day]
IR_{s-a}	=	Resident adult soil ingestion rate [mg/day]
BW_c	=	Resident child body weight [kg]
BW_a	=	Resident adult body weight [kg]
ED_c	=	Resident child exposure duration [year]
ED_a	=	Resident adult exposure duration [year]
ED_{res}	=	Resident exposure duration [year]
EF_{res}	=	Exposure frequency for a resident for direct contact pathway [days/year]
365	=	Conversion factor [days/year]
10^{-6}	=	Conversion factor [kg/mg]

2.4 Dermal Contact with Surficial Soil

Carcinogenic effects

$$RBTL_{DC\text{-}adj} = \frac{TR \times AT_c \times 365}{SF_o \times SA_{aa} \times RAF_d \times 10^{-6} \times EF_{res}}$$

Where:

$$SA_{aa} = \frac{ED_c \times M_c \times SA_c}{BW_c} + \frac{ED_a \times M_a \times SA_a}{BW_a}$$

Noncarcinogenic effects

$$RBTL_{DC} = \frac{ED_c \times THQ \times AT_{nc} \times 365 \times BW_c}{RAF_d \times EF_{dc} \times ED_c \times M_c \times SA_c \times \left(\frac{1}{RfD_o \times RAF_o}\right) \times 10^{-6}}$$

Source: EPA 2007, Appendix D, p. D-6

Where:

$RBTL_{DC\text{-}adj}$	=	Age-adjusted risk-based target level for carcinogenic effects of dermal contact with soil [mg/kg soil]
$RBTL_{DC}$	=	Risk-based target level for noncarcinogenic effects of dermal contact with soil [mg/kg soil]
TR	=	Target risk or the increased chance of developing cancer over a lifetime due to exposure to a chemical [-]
THQ	=	Target hazard quotient for individual constituents [-]
AT_c	=	Averaging time for carcinogens [years]
AT_{nc}	=	Averaging time for noncarcinogens [years]
EF_{res}	=	Exposure frequency for a resident for direct contact pathway [days/year]
RAF_d	=	Chemical-specific dermal relative absorption factor [-]
RAF_o	=	Oral relative absorption factor [-]
M_c	=	Resident child soil-to-skin adherence factor [mg/cm^2]
M_a	=	Resident adult soil-to-skin adherence factor [mg/cm^2]
RfD_o	=	Chemical-specific oral reference dose [mg/(kg-day)]
SF_o	=	Chemical-specific oral cancer slope or potency factor [mg/(kg-day)]$^{-1}$
SA_{aa}	=	Age-adjusted skin surface area [mg-yr/ kg-day]
BW_c	=	Resident child body weight [kg]
BW_a	=	Resident adult body weight [kg]
ED_c	=	Resident child exposure duration [year]
ED_a	=	Resident adult exposure duration [year]
SA_c	=	Resident child skin surface area [cm^2/day]
SA_a	=	Resident adult skin surface area [cm^2/day]
365	=	Conversion factor [days/year]
10^{-6}	=	Conversion factor [kg/mg]

2.5 Combined Direct Contact Soil Pathway: Ingestion, Inhalation of Vapors and Particulates, and Dermal Contact

Carcinogenic effects

$$RBTL_{ss-combined} = \frac{TR \times AT_c \times 365}{SF_o \times 10^{-6} \times \left[\left(IR_{s-aa} \times RAF_o\right) + \left(SA_{aa} \times RAF_d\right)\right]} + \frac{TR \times AT_c \times 365}{ED_r \times EF_{res} \times ET_{o-r} \times IUR \times \left(\frac{1}{VF} + \frac{1}{PEF}\right) \times 1000}$$

Noncarcinogenic effects

$$RBTL_{ss-combined} = \frac{THQ \times AT_{nc} \times 365}{\frac{1}{RfD_o} \times 10^{-6} \times \left[\left(\left(\frac{ED_c + EF_{res} + IR_{s-c}}{BW_c}\right) \times RAF_o\right) + \left(\left(\frac{ED_c + EF_{res} + M_c + SA_c}{BW_c}\right) \times RAF_d\right)\right]} + \frac{THQ \times AT_{nc} \times 365}{ED_r \times EF_{res} \times ET_{o-r} \times \left(\frac{1}{RfC}\right) \times \left(\frac{1}{VF} + \frac{1}{PEF}\right)}$$

Note: All parameters are defined under the individual pathway equations above (sections 2.2–2.4).

2.6 Subsurface Soil Concentrations Protective of Indoor Vapor Inhalation

$$RBTL_{si} = \frac{RBTL_{ai}}{\alpha} * EF$$

Where:

$RBTL_{si}$ = Risk-based target level for indoor inhalation of vapors from subsurface soils [mg/kg-dry soil]

$RBTL_{ai}$ = Risk-based target level for indoor inhalation of air [mg/m^3-air]

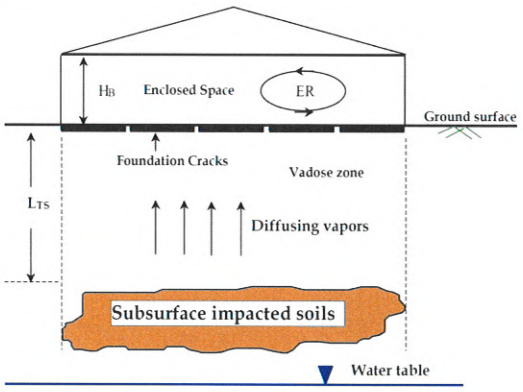
α = Chemical-specific attenuation factor from subsurface soil to indoor (enclosed space) air derived from the Johnson-Ettinger model [-]

EF = Equilibrium factor to convert vapor target level to total soil target level

$$= \frac{\Theta_{ws} + (K_D \rho_s) + (H \Theta_{as})}{(H \rho_s)} * 0.001$$

Where:

ρ_s = Dry soil bulk density [g-soil/cm^3-soil]



H = Chemical-specific Henry's Law constant [(L-H_2O)/(L-air)]

θ_{as} = Volumetric air content in the vadose zone soils [cm^3-air/cm^3-soil]

θ_{ws} = Volumetric water content in vadose zone soils [cm^3-H_2O/cm^3- soil]

K_D = $f_{oc} \times K_{oc}$ = Chemical-specific soil-water sorption coefficient [cm^3-H_2O/g-soil]

Source: Modified from EPA 2003

2.7 Ground Water Concentrations Protective of Indoor Vapor Inhalation

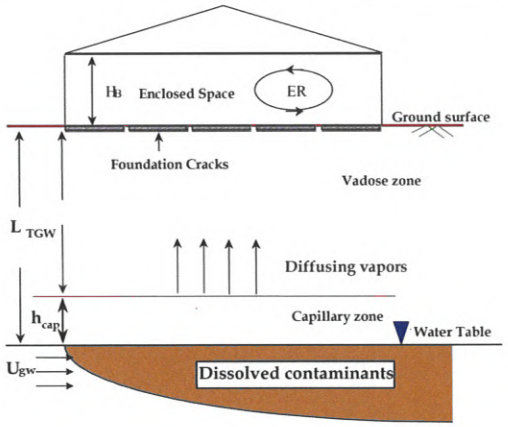
$$RBTL_{wi} = \frac{RBTL_{ai}}{\alpha} * EF$$

Where:

$RBTL_{wi}$ = Risk-based target level for indoor inhalation of vapors from ground water [mg/L-H_2O]

$RBTL_{ai}$ = Risk-based target level for indoor inhalation of air (mg/m^3-air)

α = Chemical-specific attenuation factor from ground water to indoor (enclosed space) air derived from the Johnson-Ettinger model [-]



EF = Equilibrium factor to convert vapor target level to water target level

= (1/H)*0.001m^3/L

Where:

H = Henry's Constant [-]

Source: Modified from EPA 2003

2.8 Direct Ingestion of Ground Water

Carcinogenic effects

$$RBTL_{w\text{-}adj} = \frac{TR \times AT_c \times 365}{IR_{w\text{-}aa} \times SF_o}$$

Where:

$$IR_{w\text{-}aa} = \frac{ED_c \times EF_{res} \times IR_{w\text{-}c}}{BW_c} + \frac{ED_a \times EF_{res} \times IR_{w\text{-}a}}{BW_a}$$

Noncarcinogenic effects

$$RBTL_w = \frac{THQ \times AT_{nc} \times 365 \times RfD_o \times BW_a}{IR_{w\text{-}a} \times EF_{res} \times ED_a}$$

Source: Modified from EPA 1989, p. 6-35

Where:

$RBTL_{w\text{-}adj}$	=	Age-adjusted risk-based target level for ingestion of ground water [mg/L-H_2O]
$RBTL_w$	=	Risk-based target level for ingestion of ground water [mg/L-H_2O]
TR	=	Target risk or the increased chance of developing cancer over a lifetime due to exposure to a chemical [-]
THQ	=	Target hazard quotient for individual constituents [-]
AT_c	=	Averaging time for carcinogens [years]
AT_{nc}	=	Averaging time for noncarcinogens [years]
RfD_o	=	Chemical-specific oral reference dose [mg/(kg-day)]
SF_o	=	Chemical-specific oral cancer slope or potency factor [mg/(kg-day)]$^{-1}$
$IR_{w\text{-}aa}$	=	Age-adjusted ground water ingestion rate [L/kg]
$IR_{w\text{-}c}$	=	Resident child ground water ingestion rate [L/day]
$IR_{w\text{-}a}$	=	Resident adult ground water ingestion rate [L/day]
BW_c	=	Resident child body weight [kg]
BW_a	=	Resident adult body weight [kg]
ED_c	=	Resident child exposure duration [year]
ED_a	=	Resident adult exposure duration [year]
EF_r	=	Exposure frequency for a resident [days/year]
365	=	Conversion factor [days/year]

3 Target Levels for Ground Water Resource Protection

3.1 Domenico Model: Dilution Attenuation Factor (DAF) in the Saturated Zone

Domenico model for multi-dimensional transport with decay and infinite source:

$$\frac{C(x,y,z,t)}{C_o} = (1/8)\ exp\left[\frac{x}{2\,\alpha_x}\left[1-\sqrt{1+\frac{4\,k\,\alpha_x}{v}}\right]\right]\times erfc\left[\frac{\left[(x-vt)\sqrt{1+\frac{4\,k\,\alpha_x}{v}}\right]}{2\sqrt{\alpha_x \times v \times t}}\right]\times$$

$$\left[erf\left[\frac{\left(y+\frac{W_{gw}}{2}\right)}{2\sqrt{\alpha_y\,x}}\right]-erf\left[\frac{\left(y-\frac{W_{gw}}{2}\right)}{2\sqrt{\alpha_y\,x}}\right]\right]\times\left[erf\left[\frac{\left(z+\delta_{gw}\right)}{2\sqrt{\alpha_z\,x}}\right]-erf\left[\frac{\left(z-\delta_{gw}\right)}{2\sqrt{\alpha_z\,x}}\right]\right]$$

Where:

C	=	Dissolved-phase concentration [mg/L]
C_o	=	Dissolved-phase concentration at the source (at $x = y = z = 0$) [mg/L]
v	=	Retarded seepage velocity [m/sec]
k	=	Overall first order bio-decay rate [1/day]
α_x	=	Longitudinal dispersivity [m] ($\alpha_x = x/10$)
α_y	=	Lateral dispersivity [m] ($\alpha_y = x/30$)
α_z	=	Vertical dispersivity [m] ($\alpha_z = x/200$)
x, y, z	=	Spatial coordinates [m]
t	=	Time [day]
x	=	Distance along the centerline to point of exposure from the downgradient edge of dissolved-plume, source zone, or source well [m]
W_{gw}	=	Ground water mixing zone width [m]
δ_{gw}	=	Ground water mixing zone thickness [m]
DAF	=	C_o/C

Source: Domenico 1990, Eqn. 17.21

At the centerline, for steady-state (after a long time) with decay the concentration can be obtained by setting $y = 0$, $z = 0$, and $x << v \times t$ as:

$$\frac{C(x)}{C_o} = exp\left[\frac{x}{2\,\alpha_x}\left[1-\sqrt{1+\frac{4\,k\,\alpha_x}{v}}\right]\right]\times erf\left[\frac{W_{gw}}{4\sqrt{\alpha_y\,x}}\right]\times erf\left[\frac{\delta_{gw}}{2\sqrt{\alpha_z\,x}}\right]$$

At the centerline, for steady-state the concentration without decay can be obtained by setting $y = 0$, $z = 0$, $x << v \times t$, and $k = 0$ as:

$$\frac{C(x)}{C_o} = erf\left[\frac{W_{gw}}{4\sqrt{\alpha_y\,x}}\right]\times erf\left[\frac{\delta_{gw}}{2\sqrt{\alpha_z\,x}}\right]$$

Retarded seepage velocity v is given by the equation:

$$v = \frac{U_{gw}}{R \times \theta_T}$$

Where:

U_{gw}	=	ground water Darcy velocity [m/s]
R	=	retardation factor in the saturated zone [-]
θ_T	=	Total soil porosity in the saturated zone

3.2 Soil to Ground Water Leaching Factor

$$LF_{SW} = \frac{1}{DAF_{Summers} \times K_{Water-soil}}$$

$$DAF_{Summers} = 1 + \frac{U_{gw} \times \delta_{gw}}{I \times W_{gw}} \quad \text{(The Summers Model)}$$

$$K_{Water-soil} = \frac{\theta_{ws} + K_d \rho_s + H \times \theta_{as}}{\rho_s}$$

Where:

LF_{SW}	=	Soil to ground water leaching factor [mg/L-H_20)/mg/kg-soil)]
$DAF_{Summers}$	=	Dilution attenuation factor in the mixing zone [-]
$K_{Water-soil}$	=	Water-soil partitioning coefficient [(mg/kg-soil)/(mg/L-H_2O)]
ρ_s	=	Dry soil bulk density [g-soil/cm^3-soil]
θ_{ws}	=	Volumetric water content in vadose zone soils [cm^3-H_2O/cm^3- soil]
K_d	=	$f_{oc} \times K_{oc}$
	=	Chemical-specific soil-water sorption coefficient [cm^3-H_2O/g-soil]
H	=	Chemical-specific Henry's Law constant [(L-H_2O)/(L-air)]
θ_{as}	=	Volumetric air content in the vadose zone soils [cm^3-air/cm^3-soil]
U_{gw}	=	Ground water Darcy velocity [cm/yr]
δ_{gw}	=	Ground water mixing zone thickness [cm]
I	=	Infiltration rate of water through soil [cm/year]
W_{gw}	=	Ground water mixing zone length [cm]

Source: EPA 1996

3.3 Soil Saturation Limit

$$C_s^{sat} = \frac{S}{\rho_s} \times [H \times \theta_{as} + \theta_{ws} + K_d \rho_s]$$

Where:

C_s^{SAT}	=	Soil concentration at which dissolved pore water and vapor phases become saturated [(mg/kg-soil)]
S	=	Pure component solubility in water [mg/L-H_2O]
ρ_s	=	Dry soil bulk density [g-soil/cm^3-soil]
H	=	Chemical-specific Henry's Law constant [(L-H_2O)/(L-air)]
θ_{as}	=	Volumetric air content in the vadose zone soils [cm^3-air/cm^3-soil]
θ_{ws}	=	Volumetric water content in vadose zone soils [cm^3-H_2O/cm^3- soil]
K_d	=	$f_{oc} \times K_{oc}$
	=	Chemical-specific soil-water sorption coefficient [cm^3-H_2O/g-soil]

Source: ASTM 1995

3.4 Soil and Ground Water Concentration for Ground Water Protection

$$\textit{Allowable soil concentration at the source} = \textit{Target groundwater concentration at the POE} \times \frac{DAF_{POE}}{LF_{SW}} \times DAF_{unsat}$$

$$\textit{Allowable groundwater concentration at the source} = \textit{Target groundwater concentration at the POE} \times DAF_{POE}$$

$$\textit{Allowable groundwater concentration at the POC} = \textit{Target groundwater concentration at the POE} \times \frac{DAF_{POE}}{DAF_{POC}}$$

Where:

POE	=	Point of exposure
POC	=	Point of compliance
DAF_{POE}	=	Dilution Attenuation Factor (in the saturated zone) between the point of exposure and the source
DAF_{POC}	=	Dilution Attenuation Factor (in the saturated zone) between the point of compliance and the source
DAF_{unsat}	=	Dilution Attenuation Factor (in the vadose zone) between water table and soil source
LF_{sw}	=	Dry soil leaching factor

Additional relationships used in the calculation of allowable soil and ground water concentration with chemical degradation:

$$\textit{First order decay rate} = \frac{0.693}{Half - Life}$$

$$\text{Retardation Factor for Organics in saturated zone} = 1 + \left(\frac{\rho_{ss} \times K_{ds}}{\theta_{TS}} \right)$$

Where:

ρ_{ss}	=	Dry soil bulk density of the saturated zone soil [g-soil/cm^3-soil]
K_{ds}	=	Chemical-specific soil-water distribution coefficient in the saturated zone [mL/g]
	=	$K_{oc} \times f_{ocs}$
Koc	=	Organic carbon distribution coefficient in the saturated zone [mL/g]
f_{ocs}	=	Fractional organic carbon content in the saturated zone [-]
θ_{TS}	=	Total soil porosity in the saturated zone [cm^3/cm^3-soil]

4 Volatilization Factor, Particulate Emission Factor, and Effective Diffusion Coefficients

4.1 Volatilization Factor from Surface Soil to Outdoor (ambient) Air

$$VF = Q/C \times \frac{\left(3.14 \times D_A \times \tau\right)^{1/2}}{\left(2 \times \rho_s \times D_A\right)} \times 10^{-4}$$

Where:

$$D_A = \frac{\left(\theta_{as}^{10/3} \times D^a \times H + \theta_{ws}^{10/3} \times D^w\right)/\theta_T^2}{\rho_s \times K_d + \theta_{ws} + \theta_{as} \times H}$$

Where:

VF	=	Volatilization factor from surface soil to outdoor (ambient) air [(m^3-air)/(kg-soil)]
Q/C	=	Inverse of the mean concentration at the center of square source [cm^2/s]
D_A	=	Apparent diffusivity [cm^2/s]
τ	=	Averaging time for vapor flux [s]
ρ_s	=	Dry soil bulk density [g-soil/cm^3-soil]
K_d	=	Chemical-specific solid-water sorption coefficient [cm^3-H_2O/g-soil]
D^a	=	Chemical-specific diffusion coefficient in air [cm^2/s]
D^w	=	Chemical-specific diffusion coefficient in water [cm^2/s]
θ_T	=	Total soil porosity in the impacted zone [cm^3/cm^3-soil]
θ_{as}	=	Volumetric air content in the vadose zone soils [cm^3-air/cm^3-soil]
θ_{ws}	=	Volumetric water content in the capillary fringe soils [cm^3-H_2O/cm^3-soil]
H	=	Chemical-specific Henry's Law constant [(L-H_2O)/(L-air)]
10^{-4}	=	Conversion factor [m^2/cm^2]

Source: EPA 1996

4.2 Particulate Emission Factor

$$PEF = Q/C \times \frac{3600}{0.036 \times (1 - V) \times \left(U_m / U_t\right)^3 \times F(x)}$$

Where:

PEF	=	Particulate emission factor [(m^3-air)/(kg-soil)]
Q/C	=	Inverse of the mean concentration at the center of square source [(g/m^2-s)/(kg/m^3)]
V	=	Fraction of vegetative cover [-]
U_m	=	Mean annual wind speed [m/s]
U_t	=	Equivalent threshold value of wind speed at 7 m [m/s]
$F(x)$	=	Function dependent on U_m/U_t derived using Cowherd et al. 1985 [-]
0.036	=	Empirical constant [m^2-hr/g]

Source: EPA 1996

4.3 Effective Diffusion Coefficients

4.3.1 Effective Diffusion Coefficient in Soil

$$D_s^{eff} = D^a \times \frac{\theta_{as}^{3.33}}{\theta_T^{2.0}} + D^w \times \frac{1}{H} \times \frac{\theta_{ws}^{3.33}}{\theta_T^{2.0}}$$

Where:

D_s^{eff}	=	Effective diffusion coefficient in soil based on vapor-phase concentration [cm^2/s]
D^a	=	Chemical-specific diffusion coefficient in air [cm^2/s]
D^w	=	Chemical-specific diffusion coefficient in water [cm^2/s]
θ_{as}	=	Volumetric air content in capillary fringe soils [cm^3-air/cm^3-soil]
θ_{ws}	=	Volumetric water content in capillary fringe soils [cm^3-H_2O/cm^3-soil]
θ_T	=	Total soil porosity in the impacted zone [cm^3/cm^3-soil]
H	=	Chemical-specific Henry's Law constant [(L-H_2O)/(L-air)]

4.3.2 Effective Diffusion Coefficient between Ground Water and Surface Soil

$$D_{ws}^{eff} = L_{TGW} \times \left[\frac{h_{cap}}{D_{cap}^{eff}} + \frac{\left(L_{TGW} - h_{cap}\right)}{D_s^{eff}} \right]^{-1}$$

Where:

D_{ws}^{eff}	=	Effective diffusion coefficient between ground water and surface soil [cm^2/s]
h_{cap}	=	Thickness of capillary fringe [cm]
D_{cap}^{eff}	=	Effective diffusion coefficient through capillary fringe [cm^2/s]
D_s^{eff}	=	Effective diffusion coefficient in soil based on vapor-phase concentration [cm^2/s]
L_{TGW}	=	Source-building separation [cm]

4.3.3 Effective Diffusion Coefficient In Capillary Fringe Soil

$$D_{cap}^{eff} = D^a \times \frac{\theta_{acap}^{3.33}}{\theta_T^{2.0}} + D^w \times \frac{1}{H} \times \frac{\theta_{wcap}^{3.33}}{\theta_T^{2.0}}$$

Where:

D_{cap}^{eff}	=	Effective diffusion coefficient for the capillary fringe [cm^2/s]
D^a	=	Chemical-specific diffusion coefficient in air [cm^2/s]
D^w	=	Chemical-specific diffusion coefficient in water [cm^2/s]
θ_{acap}	=	Volumetric air content in capillary fringe soils [cm^3-air/cm^3-soil]
θ_{wcap}	=	Volumetric water content in capillary fringe soils [cm^3-H_2O/cm^3-soil]
θ_T	=	Total soil porosity [cm^3/cm^3-soil]
H	=	Chemical-specific Henry's Law constant [(L-H_2O)/(L-air)]

Source: ASTM 1995

4.3.4 Effective Diffusion Coefficient In Foundation/Wall Cracks

$$D_{crack}^{eff} = D^a \times \frac{\theta_{acrack}^{3.33}}{\theta_T^{2.0}} + D^w \times \frac{1}{H} \times \frac{\theta_{wcrack}^{3.33}}{\theta_T^{2.0}}$$

Where:

D_{crack}^{eff}	=	Effective diffusion coefficient through foundation cracks [cm^2/s]
D^a	=	Chemical-specific diffusion coefficient in air [cm^2/s]
D^w	=	Chemical-specific diffusion coefficient in water [cm^2/s]
θ_{acrack}	=	Volumetric air content in foundation/wall cracks [cm^3-air/cm^3-total volume]
θ_{wcrack}	=	Volumetric water content in foundation/wall cracks [cm^3-H_2O/cm^3-total volume]
θ_T	=	Total soil porosity [cm^3/cm^3-soil]
H	=	Chemical-specific Henry's Law constant [(L-H_2O)/(L-air)]

4.4 Water Content in Soil in the Capillary Fringe

$$\theta_{wcap} = \theta_r + \frac{\theta_{Tcap} - \theta_r}{\left[1 + (\alpha h)^N\right]^M}$$

Where:

θ_{wcap}	=	Water content in the capillary fringe zone soil [cm^3-water/cm^3-soil]
θ_r	=	Residual soil water content [cm^3-water/cm^3-soil]
θ_{Tcap}	=	Total porosity of soil in the capillary fringe zone [cm^3-voids/cm^3-soil]
α	=	Point of inflection in the water retention curve where $d\theta_w/dh$ is maximal [1/cm]
h	=	Air-entry pressure head [cm]
	=	$1/\alpha$ and assumed to be positive
N	=	Van Genuchten curve shape parameter [-]
M	=	$1 - (1/N)$

Appendix F: Methodology and Example Calculation for Remedial Action Target Levels

This page intentionally left blank for correct double-sided printing.

Introduction

For each receptor, the cumulative risk for carcinogenic effects and hazard index (HI) for noncarcinogenic effects at a site for all petroleum chemicals of interest (COIs) and complete routes of exposures (ROE) (except ingestion of water) should not exceed 1×10^{-5} and 1, respectively. This appendix describes the default methodology used by the Idaho Department of Environmental Quality (DEQ) to apportion risk and derive remedial action target level (RATL) concentrations for petroleum COIs in various media at sites where the risk or hazard is estimated to exceed the acceptable target risk level or acceptable HI.

Developing Target Levels: Method

The default method for developing target levels can be summarized by the following steps:

Step 1: Based on complete or potentially complete routes of exposure identified earlier and estimated representative concentrations, calculate the corresponding risk ($Risk_{i,j}^{rep}$) and hazard quotient ($HQ_{i,j}^{rep}$) for each chemical (i) for each complete pathway (j).

Results can be used to generate a matrix of risk and hazard quotient (HQ) values as shown in Table 1 below.

Table 1. Example matrix for calculation of remedial action target levels

Petroleum Chemical of Interest	Pathway 1		Pathway 2		Pathway 3		Cumulative		Number of Pathways	
	Risk	HQ	Risk	HQ	Risk	HQ	Risk	HI	Carcino-genic	Noncarcino-genic
C1	X	N/A	X	N/A	—	N/A	SUM	SUM	2	0
C2	N/A	X	N/A	X	N/A	X	SUM	SUM	0	3
C3	N/A	X	—	X	N/A	X	SUM	SUM	0	3
C4	X	N/A	X	N/A	X	N/A	SUM	SUM	3	0
C5	X	X	N/A	X	N/A	X	SUM	SUM	1	3
Cumulative							$Risk_{site}$ = SUM(SUM)	HI_{site} = SUM(SUM)	6	9

Note: **X** indicates pathway complete
N/A indicates not applicable because there is no relevant toxicity data or physical-chemical property.
A dash (—) indicates the value was not calculated because there was no entry under representative concentrations. This could mean that the chemical is not a petroleum chemical of interest for the pathway being evaluated based on release history or based on site characterization data.

Step 2: Calculate cumulative risk (site risk) and site HI.

$$Risk_{site} = \sum_{i=1}^{n_c} \sum_{j=1}^{m_i} Risk_{i,j}$$

$$HI_{site} = \sum_{i=1}^{n_{nc}} \sum_{j=1}^{m_i} HQ_{i,j}$$

Where:

$Risk_{i,j}$ = risk from exposure to chemical i through pathway j

$HQ_{i,j}$ = hazard quotient for exposure to chemical i through pathway j

m_i = number of complete pathways for chemical i (the suffix to m indicates that the number of complete pathways can be different for different chemicals)

n_c = number of carcinogenic chemicals at the site

n_{nc} = number of noncarcinogenic chemicals at the site

If the cumulative risk and HI for all the receptors at the site are below the acceptable levels, the site does not require the development of RATL. Site closure may be appropriate if other required regulatory issues have been resolved.

Step 3: Determine the number of chemical-pathway combinations (for carcinogens and noncarcinogens separately) at the site.

For the number of chemical-pathway combinations for carcinogens,

$$N_c = \sum_{i=1}^{n_c} \sum_{j=1}^{m_i} p_{i,j}$$

For the number of chemical-pathway combinations for non-carcinogens,

$$N_{nc} = \sum_{i=1}^{n_{nc}} \sum_{j=1}^{m_i} p_{i,j}$$

Where:**Error! Objects cannot be created from editing field codes.**

$p_{i,j}$ = complete pathway for chemical i and pathway j

m_i = number of complete pathways for chemical i (the suffix to m indicates that the number of complete pathways can be different for different chemicals)

n_c = number of carcinogenic chemicals at the site

n_{nc} = number of noncarcinogenic chemicals at the site

Note that some chemicals show both carcinogenic and noncarcinogenic toxicity and should be counted in both categories. For example, chemical C5 in the example above (Table 1) has 3 complete pathways for the noncarcinogenic effects and 1 pathway for the carcinogenic effects.

Step 4: Based on equal apportioning of target cumulative risk and HI, compute allocated risk and HQ contribution by chemical *i* through pathway *j* using the following equations:

$$Risk_{i,j}^{allocated} = \frac{1 \times 10^{-5}}{N_c}$$

$$HQ_{i,j}^{allocated} = \frac{1}{N_c}$$

Step 5: Estimate the risk reduction factor (RRF) in risk or HQ required so the contribution by chemical *i* acting through pathway *j* is equal to the allocated risk or allocated HQ.

Calculate the RRF for chemical *i* acting through pathway *j* with the following equation:

$$RRF_{i,j} = \frac{Risk_{i,j}^{rep}}{Risk_{i,j}^{allocated}}$$

Calculate the hazard quotient reduction factor (HQRF) for chemical *i* acting through pathway *j* with the following equation:

$$HQRF_{i,j} = \frac{HQ_{i,j}^{rep}}{HQ_{i,j}^{allocated}}$$

Step 6: Calculate the target level (i.e., allowable concentration) for chemical *i* acting through pathway *j*.

For carcinogens,

$$C_{i,j}^{allowable} = \frac{C_{i,j}^{rep}}{RRF_{i,j}}.$$

For noncarcinogens,

$$C_{i,j}^{allowable} = \frac{C_{i,j}^{rep}}{HQRF_{i,j}}.$$

If a chemical has $C_{i,j}^{allowable}$ based on carcinogenic and noncarcinogenic toxicity, the applicable RATL for that chemical should be the lower of the two allowable concentrations.

Developing Target Levels: Example

The following is an example of the target level calculations described above. Table 2 presents fictitious representative concentrations for each of five chemicals and three pathways (two soil and one ground water).

Table 2. Fictitious representative concentrations used in target level calculation example

Petroleum Chemical of Interest	Pathway 1 (milligrams/ kilogram)	Pathway 2 (milligrams/ kilograms)	Pathway 3 (milligrams/ liter)
C1	1	2	—
C2	2	4	2
C3	3	6	3
C4	4	8	4
C5	5	10	5

Step 1: Use these representative concentrations to calculate risk and HQ for each chemical and pathway the chemical acts through. The resulting matrix of risk and HQ values are shown in Table 3.

Table 3. Example of risk/chemical-of-interest/pathway matrix for target level calculation

Petroleum Chemical of Interest	Pathway 1		Pathway 2		Pathway 3		Cumulative		Number of Pathways	
	Risk	HQ	Risk	HQ	Risk	HQ	Risk	HI	Carcino-genic	Noncarcino-genic
C1	1E-5	N/A	2E-5	N/A	N/A	N/A	3E-5	N/A	2	0
C2	N/A	1	N/A	3	N/A	1	N/A	5	0	3
C3	N/A	1	—	1	N/A	3	N/A	5	0	3
C4	1E-5	N/A	1E-5	N/A	1E-5	N/A	3E-5	N/A	3	0
C5	2E-5	1	N/A	1	N/A	1	2E-5	3	1	3
Cumulative							$Risk_{site}$ = 8E-5	HI_{site} = 13	6	9

Note: **N/A** indicates not applicable because there is no relevant toxicity data or physical-chemical property. **A dash (—)** indicates the value was not calculated because there was no entry under representative concentrations. This could mean that the chemical is not a petroleum chemical of interest for the pathway being evaluated based on release history or based on site characterization data.

Step 2: Calculate the cumulative site risk and HI for all chemicals and pathways for a given receptor. (In this case, the site risk and HI are 7×10^{-5} and 13, respectively.)

Step 3: Determine the number of chemical-pathway combinations (for carcinogens and noncarcinogens separately) at the site. In this example, the number of chemical-pathway combinations for carcinogens is 6, and the number of chemical-pathway combinations for noncarcinogens is 9.

Step 4: Based on equal apportioning of the target cumulative risk and HI, calculate the allocated risk and HQ contribution by chemical *i* through pathway *j*.

$$Risk_{i,j}^{allocated} = \frac{1 \times 10^{-5}}{6} = 1.7 \times 10^{-6}$$

$$HQ_{i,j}^{allocated} = \frac{1}{9} = 0.11$$

Step 5: Estimate the RRF in risk or HQ required so that the contribution by a given chemical acting through a particular pathway is equal to the allocated risk or allocated HQ.

The RRF for chemical *i* acting through pathway *j* is found with the following equation:

$$RRF_{i,j} = \frac{Risk_{i,j}^{rep}}{Risk_{i,j}^{allocated}}$$

The HQ reduction factor for chemical *i* acting through pathway *j* is calculated with the following equation:

$$HQRF_{i,j} = \frac{HQ_{i,j}^{rep}}{HQ_{i,j}^{allocated}}$$

The calculations of the RFs for the example are presented in Table 4. At actual sites, the reduction factors are rarely as uniform as they are in the example.

Table 4. Reduction factor example for target level calculations

Petroleum Chemical of Interest	Pathway 1		Pathway 2		Pathway 3	
	RRF	HQRF	RRF	HQRF	RRF	HQRF
C1	1E-5/1.7E-6 = 6.0	N/A	2E-5/1.7E-6 = 12	N/A	—	N/A
C2	N/A	1/0.11 = 9.0	N/A	3/0.11 = 27	N/A	1/0.11 = 9.0
C3	N/A	1/0.11 = 9.0	—	1/0.11 = 9.0	N/A	3/0.11 = 27
C4	1E-5/1.67E-6 = 6.0	N/A	1E-5/1. 7E-6 = 6.0	N/A	1E-5/1. 7E-6 = 6.0	N/A
C5	2E-5/1.67E-6 = 12	1/0.11 = 9.0	N/A	1/0.11 = 9.0	N/A	1/0.11 = 9.0

Note: **N/A** indicates not applicable because there is no relevant toxicity data or physical-chemical property.
A dash (—) indicates the value was not calculated because there was no entry under representative concentrations. This could mean that the chemical is not a petroleum chemical of interest for the pathway being evaluated based on release history or based on site characterization data.

Step 6: Calculate the target level for a chemical acting through a given pathway.

For carcinogens,

$$C_{i,j}^{allowable} = \frac{C_{i,j}^{rep}}{RRF_{i,j}};$$

and for non-carcinogens,

$$C_{i,j}^{allowable} = \frac{C_{i,j}^{rep}}{HQRF_{i,j}}.$$

The resulting RATL calculations, carcinogenic and/or noncarcinogenic, for the example are presented in Table 5. The RATL concentrations are presented in bold.

Table 5. Example remedial action target level (RATL) concentrations for target level calculations

Petroleum Chemical of Interest	Pathway 1 (milligrams/kilogram)		Pathway 2 (milligrams/kilogram)		Pathway 3 (milligrams/liter)	
	$RATL_c$	$RATL_{nc}$	$RATL_c$	$RATL_{nc}$	$RATL_c$	$RATL_{nc}$
C1	1/6.0 = **0.17**	N/A	2/12 = 0.17	N/A	—	N/A
C2	N/A	2/9.0 = 0.22	N/A	4/27= **0.15**	N/A	2/9.0 = **0.22**
C3	N/A	3/9.0 = **0.33**	—	6/9.0 = 0.67	N/A	3/27 = **0.11**
C4	4/6.0 = **0.67**	N/A	8/6.0 = 1.3	N/A	4/6.0 = **0.67**	N/A
C5	5/12 = **0.42**	5/9.0 = 0.56	N/A	10/9.0 = 1.1	N/A	5/9.0 = **0.56**

Note: **N/A** indicates not applicable because there is no relevant toxicity data or physical-chemical property.
A dash (—) indicates the value was not calculated because there was no entry under representative concentrations. This could mean that the chemical is not a petroleum chemical of interest for the pathway being evaluated based on release history or based on site characterization data.

In this example, for chemical C5 and pathway P1, both carcinogenic and noncarcinogenic RATLs are calculated. The lower of the two, 0.42 milligrams/kilogram (the carcinogenic RATL), would be used.

Disclaimer

This document presents current technical recommendations of the U.S. Environmental Protection Agency (EPA) based on our current understanding of petroleum vapor intrusion (PVI) into indoor air from subsurface sources. This document provides technical information to EPA, state, tribal, and local agencies. It also informs the public and the regulated community on how EPA intends to implement its regulations. This guidance document does not impose any requirements or obligations on the EPA, the states, or local or tribal governments, or the regulated community. Rather, the sources of authority and requirements for addressing subsurface vapor intrusion are the relevant statutes and regulations. Decisions regarding a particular situation should be made based upon statutory and regulatory authority. Decision-makers retain the discretion to adopt or approve approaches on a case-by-case basis that differ from this document. Contact information for your state's UST-implementing agency may be found at *http://www.epa.gov/oust/states/statcon1.htm*. EPA may revise this document in the future, as appropriate.

REC 4649

TR 1334

Recommendations

This document provides technical information to regulatory personnel from the U.S. Environmental Protection Agency (EPA) and state[1], tribal, and local agencies for investigating and assessing petroleum vapor intrusion (PVI) at sites where petroleum hydrocarbons (PHCs) have been released from underground storage tanks (USTs). This document is comprised of two parts: *Recommendations*, which provides a description of EPA's recommended approach for addressing PVI, and *Supporting Technical Information*, which provides detailed technical information supporting the recommendations.

Background

In 2002, EPA's Office of Solid Waste and Emergency Response (OSWER) issued draft vapor intrusion guidance, *OSWER Draft Guidance for Evaluating the Vapor Intrusion to Indoor Air Pathway from Groundwater and Soils (Draft Vapor Intrusion Guidance)* (EPA, 2002).[2] This draft guidance explicitly states that it is not recommended for addressing petroleum vapor intrusion (PVI) at UST sites regulated under Subtitle I of the Solid Waste Disposal Act through the Hazardous and Solid Waste Amendments of 1984.

In 2009, EPA's Office of Underground Storage Tanks (OUST), at the request of partners and stakeholders, initiated a collaborative effort to develop a technical guide for petroleum vapor intrusion. Further highlighting the need for information on PVI, EPA's Office of Inspector General later that year released an evaluation report, *Lack of Final Guidance on Vapor Intrusion Impedes Efforts to Address Indoor Air Risks* (Report No. 10-P-0042).[3] The report included recommendations, one of which was for EPA to issue final vapor intrusion guidance that incorporates information on how risks from petroleum hydrocarbon vapors should be addressed. In response to stakeholder requests, EPA's Office of Underground Storage Tanks developed this technical guide, which is a companion to OSWER's more general vapor intrusion guide.[4] Together, these two documents replace the 2002 Draft Vapor Intrusion Guide.

EPA developed the two guides to address different scenarios and meet the needs of different audiences. The UST program regulates a very large universe of sites, typically gas stations, which share many similar characteristics, including small release volumes (compared to pipelines and tank farms, for example) and the potential for aerobic biodegradation of petroleum vapors. Based on these facts, and to meet the request of UST regulators and practitioners, EPA developed a guide specifically focused on petroleum UST releases. This PVI guide provides screening criteria based on physical separation distances between vapor sources and potential receptors. EPA OUST derived the screening criteria from an analysis of a large

REC 4650

TR 1335

data set of samples from leaking UST sites.[5] In contrast, the OSWER Vapor Intrusion Guide addresses a wide variety of sites and a broader range of contaminants.

Overview Of Petroleum Vapor Intrusion

Vapor intrusion is the general term given to migration of volatile organic chemicals (VOCs) from any subsurface contaminant source, such as contaminated soil or groundwater, through the soil and into an overlying building. There are two general classes of VOCs that account for a large number of soil and groundwater contamination sites in the United States:

- Petroleum hydrocarbons (PHCs) and non-PHC fuel additives
- Chlorinated solvents (e.g., the dry cleaning chemical tetrachloroethylene, also known as perchloroethylene, (PCE), and the degreasing solvents trichloroethylene (TCE), 1,1,1-trichloroethane (TCA)).

In this guide, petroleum vapor intrusion (PVI) is defined as the intrusion of vapors from subsurface PHCs and non-PHC fuel additives into overlying or nearby buildings or structures.

Vapors emanating from petroleum-contaminated soil or groundwater that enter buildings may result in indoor air concentrations that pose a risk to building occupants. PVI may pose both immediate threats to safety (e.g., fire or explosion potential from petroleum vapors or methane) and possible adverse health effects from inhalation of toxic chemicals (e.g., exposure to benzene from gasoline). PVI may be associated with three groups of volatile chemicals:

- PHCs found in gasoline, diesel, and jet fuel (e.g., benzene, trimethylbenzenes (TMBs), naphthalene)
- Volatile chemicals other than PHCs that may be found in petroleum fuels, such as ethers, alcohols, and other fuel additives (e.g., methyl tertiary-butyl ether (MTBE), tertiary-butyl alcohol (TBA), ethylene dibromide (EDB), and 1,2-dichloroethane (1,2-DCA))
- Methane, which is generated from anaerobic biodegradation of PHCs and other constituents of petroleum fuels (especially ethanol), and organic matter in soil

In contrast to chlorinated solvents, PHCs generally biodegrade rapidly under aerobic conditions and if biodegradation is complete, produce only water and carbon dioxide. If biodegradation is incomplete a variety of intermediate degradation products may be formed, but these are usually less toxic than the parent PHCs.[6] If chlorinated solvents biodegrade it is usually under

---

[5] *Evaluation Of Empirical Data To Support Soil Vapor Intrusion Screening Criteria For Petroleum Hydrocarbon Compounds* (EPA 510-R-13-001), accessible at http://www.epa.gov/oust/cat/pvi/PVI_Database_Report.pdf

[6] Some petroleum hydrocarbons may also degrade anaerobically and may produce methane, particularly if the source is from an ethanol-blended gasoline. A recent modeling study cautions that for releases of high ethanol fuel blends (i.e., greater than E-20) advective methane transport may result in methane buildup inside buildings and pose a risk of explosion (Ma, et al., 2014, Numerical Model Investigation for Potential Methane Explosion and Benzene Vapor Intrusion Associated with High-Ethanol Blend Releases, *Environmental Science and Technology* 48(1):474-481).

anaerobic conditions, which is slower and may produce intermediate degradation products that are more toxic than the parent compounds.

The aerobic biodegradability of PHCs typically reduces the potential for PVI and justifies a different approach for addressing PVI than for vapor intrusion from chlorinated solvents and other non-aerobically biodegradable VOCs.[7]

Scope And Applicability

This PVI guide focuses on releases of petroleum-based fuels (e.g., gasoline, diesel), including both PHCs and non-PHC fuel additives, from underground storage tanks (USTs) regulated under Subtitle I of the Solid Waste Disposal Act of 1984, which are typically located at gas stations.[8] This guide applies to new and existing releases of PHCs and non-PHC fuel additives from leaking USTs and to previously closed sites where the implementing agency has reason to suspect that there may be a potential for PVI. Although EPA developed the PVI guide based on data from typical UST sites, this technical guide may also be helpful when addressing petroleum contamination at comparable non-UST sites. Petroleum contamination at sites that are not comparable to UST sites (such as refineries, petrochemical plants, terminals, aboveground storage tank farms, pipelines, and large scale fueling and storage operations at federal facilities), or sites with releases of non-petroleum chemicals including comingled plumes of petroleum and chlorinated solvents regardless of the source, should be addressed under OSWER's more general vapor intrusion guide.

This PVI guide does not impose legally binding requirements on implementing agencies or the regulated community. Decision-makers retain the discretion to adopt or approve approaches on a case-by-case basis that differ from this technical guide.

Recommended Actions For Addressing PVI

Addressing the potential for PVI is an integral part of the normal response to a suspected or confirmed release from any Subtitle I regulated UST system. At any leaking UST site, it is important to have a thorough understanding of the release (i.e., source, composition, and magnitude) and other factors that may influence the distribution and transport of contaminants that impact human safety and health. Until it is clear that human health and the environment are adequately protected from adverse impacts caused by the release, appropriate site characterization, risk assessment, and corrective action activities should continue.

---

[7] For more information on the differences between PHCs and chlorinated solvents, see *Petroleum Hydrocarbons And Chlorinated Solvents Differ In Their Potential For Vapor Intrusion* (http://www.epa.gov/oust/cat/pvi/pvicvi.pdf)

[8] EPA's UST regulations are contained in 40 CFR Parts 280, 281, and 282.50-282.105 (see http://www.epa.gov/oust/fedlaws/cfr.htm). Definitions of key terms such as UST and petroleum are found in 40 CFR 280. These definitions may change if the regulations are revised in the future.

EPA recommends the following actions for situations in which EPA, state, tribal, and local agencies are investigating releases of petroleum-based fuels (including addressing potential risks due to PVI) at leaking UST sites or where 40 CFR 280 requires[9] UST owners and operators to undertake release investigation and corrective action activities:

- ✓ **Assess and mitigate immediate threats to safety – see Section 1** (p.11)
  Identify whether there is a potential threat of explosion or fire due to the presence of flammable PHCs and non-PHC fuel additive vapors or methane[10]. A threat could be indicated by reports of the presence of odors, disagreeable taste of water, or visible signs of PHC contamination by building occupants. If so, alert first responders so they can, if necessary, evacuate these buildings until the potential threat to human safety from fire or explosion due to PVI has been assessed and mitigated as needed.

- ✓ **Conduct a site characterization and develop a conceptual site model (CSM) – see Section 3** (p.39)
  Site characterization data should be integrated into a conceptual site model (CSM). This includes characterization of the physical, biological, and chemical systems at the site, with emphasis on determining the spatial and temporal relationships between receptors and sources of contamination. The CSM should be used as the basis for planning the PVI investigation and making informed risk management decisions about the site and the threat posed by PVI to nearby receptors. EPA recommends that the site characterization include:

  - Determining the full extent and location of contamination and its nature
  - Assessing the potential for biodegradation of PHCs (and non-PHC fuel additives)
  - Defining the hydrologic and geologic characteristics of the site
  - Identifying potential receptors in the vicinity
  - Determining whether preferential transport pathways are present and connect PHC vapor sources with potential receptors[11]
  - Considering whether there are any other factors that may preclude the use of screening criteria

---

[9] In the case of a suspected or confirmed release from a regulated UST system, Subparts E and F of 40 CFR 280 require owners and operators to investigate, report, and perform corrective action (including recovery of light non-aqueous phase liquid (LNAPL) to the maximum extent practicable) if contamination is present, and submit timely reports of activities and findings to the implementing agency.

[10] Note that methane cannot be detected based on odor, taste or visible signs. Methane-detecting devices must be used. For additional information on evaluating the presence of methane and potential hazards, see ASTM's "New Practice for Evaluating Potential Hazard Due to Methane in the Vadose Zone", which is accessible at *http://www.astm.org/DATABASE.CART/WORKITEMS/WK32621.htm*.

[11] Preferential transport pathways can short-circuit the protectiveness provided by the extent of the lateral inclusion zone and the vertical separation distances described in this guide. If preferential transport pathways connect a vapor source directly to a building, indoor air sampling paired with sub-slab vapor sampling is recommended.

- ✓ **Delineate a lateral inclusion zone – see Section 4** (p.44)
  Delineate a lateral inclusion zone to focus the investigation on buildings located within these boundaries. The lateral inclusion zone is based on the spacing between clean monitoring points; the closer the spacing of the clean monitoring points, the less extensive the lateral inclusion zone.

- ✓ **Determine vertical separation distances for each building within the lateral inclusion zone – see Section 5** (p.48)
  Further narrow the investigation to potential receptors (e.g., buildings) within the lateral inclusion zone and directly overlie contamination. For such buildings, determine the vertical distance between the contamination and the building basement, foundation, or slab. This distance is determined by collecting soil gas, soil, and groundwater samples as necessary. The thickness of clean soil separating contamination from the deepest point of the building basement, foundation, or slab is the vertical separation distance.

  Additional investigation is generally unnecessary if the vertical separation distance is greater than 6 feet for dissolved contamination beneath buildings of any size, or 15 feet for light non-aqueous phase liquid (LNAPL) if the overlying building has at least one side shorter than 66 feet in length. If the distance to contamination is less than the appropriate vertical separation distance (i.e., 6 feet or 15 feet; see **Section 5**), then additional investigation is recommended.

- ✓ **Evaluate vapor source and attenuation of PHC vapors – see Section 5** (p.48), **Section 8** (p.66), **Section 9** (p.75), **Section 10** (p.81), **Section 12** (p.100), **and Section 13** (p.106)
  If contamination (either dissolved, or LNAPL whether mobile or residual) is in direct contact with a building EPA recommends indoor air sampling. In the case of direct contact, sub-slab samples cannot be collected because there is no subsurface soil between the contamination and the building. Where contamination is not in direct contact with an overlying building, then choose one of two options: (1) collect near-slab (exterior) shallow soil gas samples paired with deep (source) soil gas samples, or (2) collect indoor air samples paired with sub-slab soil gas samples. If the potential for PVI cannot be ruled out based on near-slab and deep soil gas sampling, then EPA recommends indoor air sampling paired with sub-slab vapor sampling. If the attenuation factor calculated from results of analysis of the chosen pair or vapor samples indicates that there may be a potential for PVI above applicable exposure limits, EPA recommends gathering additional information and data to determine whether mitigation is appropriate.

- ✓ **Mitigate PVI, as appropriate – see Section 1** (p.11)
  Mitigation involves interruption of the transport pathway for vapors between the source of contamination and potential receptors. Select a remedial design that is appropriate for the building and site. As necessary, establish institutional controls to limit or prohibit access to affected areas. Remediate the source of the contamination, including recovery of LNAPL (if present) to the maximum extent practicable.

Community Engagement

When conducting PVI assessments and follow-up actions, it is important to consider proactive community engagement. EPA acknowledges there is no single correct approach to engage the potentially impacted community in cleanup decisions. Community engagement can occur at any step in the process and may occur more than once. It is generally recognized that earlier and more frequent communication yields positive results, particularly for sites that pose a threat to human health or the environment, or when the public expresses an elevated level of concern or interest in the site. Depending on site circumstances, obtaining meaningful community input is a sound approach that may result in better-informed decisions. EPA developed several community engagement resources, which are available on the Office of Underground Storage Tanks website: Community Engagement And The Underground Storage Tank Program.[12] Some of the resources include:

- Guidelines For Tailoring Community Engagement Activities To Circumstances At Leaking Underground Storage Tank Sites.
- Community Engagement Resources (Toolbox) For Underground Storage Tank Programs.

Table 1 and **Figure 1** briefly outline the **Recommended Actions for Addressing PVI**. Note that this process is not necessarily linear and some of these activities may occur in a different order or recur throughout the PVI investigation; this is especially true for community engagement. Additional technical information is presented in the second part of this guide, *Supporting Technical Information.*

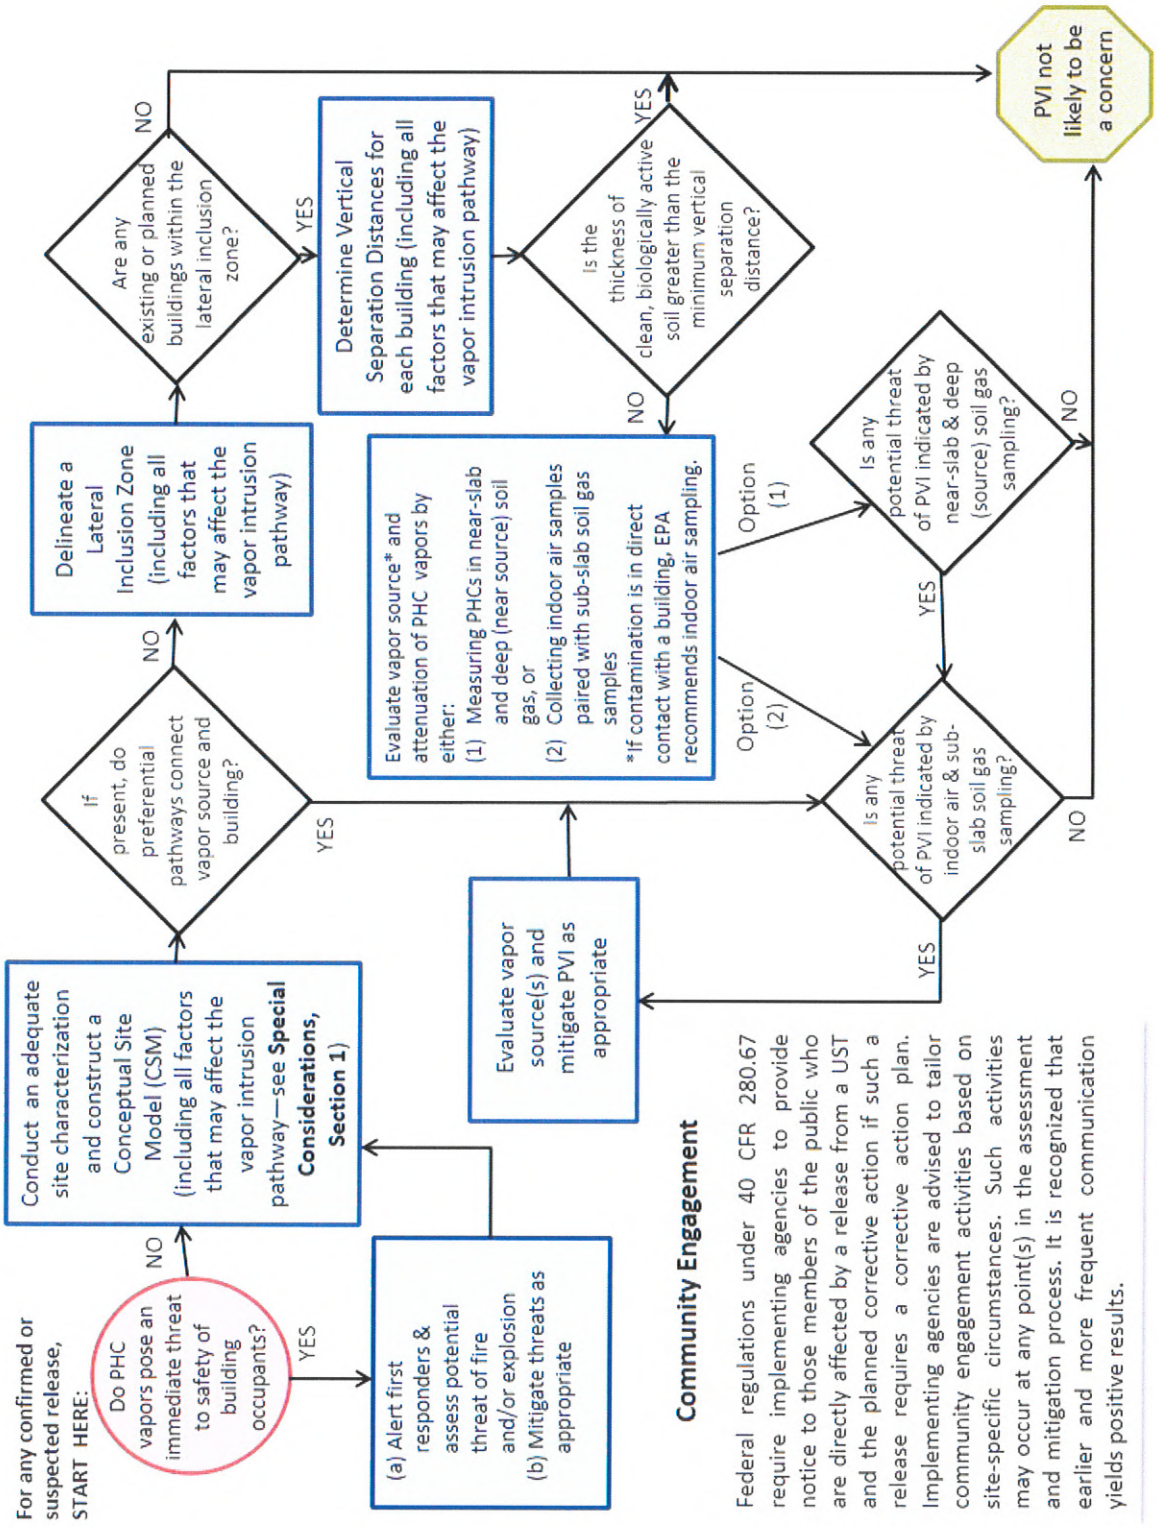
REC 4655



TR 1340

Table 1. Recommended Actions For Addressing PVI At Leaking Underground Storage Tank Sites

Recommended Actions	Purpose And Objectives	Procedures
Assess and mitigate immediate threats to safety (see Section 1, p.11)	Identify potential threat of explosion or fire due to petroleum vapors or methane. Threat may be indicated by: • LNAPL visible in building, possibly as sheen in sump • Noticeable petroleum odor; headache, dizziness, or nausea • Atypical, unusual, or disagreeable taste or smell in the water supply NOTE: Methane cannot be detected on the basis of odor, taste, or visible signs	• Investigate all reports of petroleum odors and other indicators within buildings • Detection of the presence of methane; requires specialized devices • Alert first responders so that they can, if necessary, evacuate building occupants as necessary until the potential for fire or explosion has been assessed and mitigated as needed
Conduct a site characterization and develop a conceptual site model (CSM) (see Section 3, p.39)	Characterize the physical, biological and chemical systems at the site, with emphasis on determining the spatial and temporal relationship between receptors and sources of contamination by: • Determining the full extent and location of contamination and its nature • Assessing the potential for biodegradation of PHCs • Defining the hydrologic and geologic characteristics of the site • Identifying potential receptors in the vicinity • Identifying whether preferential transport pathways are present and connect PHC vapor sources with potential receptors. Preferential transport pathways Include both natural (i.e., geologic) and man-made (i.e., underground utilities, excavations) features.	• Collect sufficient site data and information to construct CSM • Identify data gaps • Update CSM as new data become available • Where preferential transport pathways connect PHC vapor sources to receptors (e.g., buildings), indoor air sampling paired with sub-slab vapor sampling is recommended
Delineate a lateral inclusion zone (see Section 4, p.44)	Screen out buildings that are not likely to be impacted by PVI to narrow the investigation to only those buildings that have a greater potential for PVI and for which further investigation should be conducted. The lateral inclusion zone is site-specific and: • Based on the extent of contamination and distance between clean monitoring points • Decreases in extent as additional data are collected to reduce uncertainty in the CSM	• Construct lateral inclusion zone based on distance between clean monitoring points (includes consideration of the presence of preferential transport pathways)
Determine vertical separation distances (see Section 5, p.48)	Further screen out buildings that are not likely to be impacted by PVI to focus the investigation on potential receptors that overlie contamination in the dissolved, vapor, and/or LNAPL phase. The vertical separation distance is: • The thickness of clean, biologically-active soil	• For each building within the lateral inclusion zone, collect additional soil gas, soil, and groundwater samples as necessary to determine the vertical separation distance. Additional investigation is generally unnecessary

Recommended Actions	Purpose And Objectives	Procedures
	(see **Section 9**, p.75) separating contamination from overlying buildings or other potential receptors • Determined by site-specific sampling to determine the depth at which contamination is present	If the distance to contamination is greater than: • 6 feet for dissolved contamination beneath buildings of any size, or • 15 feet for LNAPL if the overlying building has at least one side shorter than 66 feet in length • If the distance to contamination is less than those indicated above, then additional investigation is recommended.
Evaluate vapor source and attenuation of PHC vapors (see Section 5, p.48, Section 8, p.66, Section 9, p.75, Section 10, p.81, Section 12, p.100, and Section 13, p.106)	Carefully evaluate the potential for PVI into those buildings identified as being the most likely to be impacted by PVI. This is a building-by-building evaluation based on sampling conducted within close proximity to the building or inside the building as necessary.	If contamination is in direct contact with building basement, foundation, or slab, then collect indoor air samples. Otherwise choose either option (1) or (2) below: 1. Collect near-slab soil gas samples coupled with deep (source) soil gas samples. If a potential threat of PVI is indicated, then proceed to option 2. If not, PVI is not likely to be a concern. 2. Collect indoor air samples paired with sub-slab soil gas samples. If these results indicate a potential threat of PVI, mitigate PVI as appropriate.
Mitigate PVI as appropriate (see Section 1, p.11)	Interrupt the pathway between the source of contamination and potential receptors. • Numerous approaches depending on building characteristics	• Select a remedial design that is appropriate for building and site • Remediate source of contamination, including recovery of LNAPL (if present) to the maximum extent practicable • Establish institutional controls to limit or prohibit access to affected areas of building, as necessary

1. Petroleum Vapor Intrusion (PVI)

Description

Petroleum vapor intrusion (PVI) occurs when vapors from petroleum hydrocarbons (PHCs) migrate through the subsurface into overlying or nearby buildings. Fuels such as gasoline, diesel, aviation gasoline, and jet fuel are comprised primarily of PHCs with some non-petroleum based additives. Under certain circumstances, PVI may result in indoor air concentrations that pose a risk to building occupants. PVI may pose immediate threats to safety (e.g., fire or explosion potential from petroleum vapors or methane) or possible adverse health effects from inhalation of toxic chemicals (e.g., exposure to benzene from gasoline). Vapor concentrations generally decrease with increasing distance from a subsurface vapor source due to aerobic biodegradation, and eventually at some distance the concentrations become negligible.

Composition Of Petroleum Fuels

Petroleum fuels are comprised of hundreds of individual compounds. PHCs present in petroleum fuels generally belong to one of two major groups: aromatics and aliphatics. The aromatic PHCs are characterized as having one or more benzene rings. Benzene, toluene, ethylbenzene, and the three isomers of xylene are collectively referred to as BTEX. The aliphatics are non-aromatic PHCs consisting of straight-chains, branched chains, or non-aromatic rings. Although BTEX represent the group of PHCs that receive the most attention at typical leaking underground storage tank (UST) sites, they are not the only compounds that may pose a risk to human health.[13] Petroleum fuels may also contain a variety of non-PHC volatile organic chemicals (VOCs) as additives to enhance performance. Fuel oxygenates such as methyl

[13] The federal UST program does not prescribe human health values for contaminants; implementing authorities should use exposure values and attenuation factors appropriate for the contaminants present and the characteristics of exposure (e.g., residential vs industrial). Although there is a lack of toxicological data for many PHCs, EPA provides some information that may be applicable. For example, EPA provides vapor intrusion screening levels (VISLs) for a variety of volatile chemicals known to pose a potential cancer risk or noncancer hazard through the inhalation pathway. These VISLs, which are calculated by the VISL Calculator (EPA, 2014b), are generally recommended, medium-specific, risk-based screening-level concentrations intended for use in identifying areas or buildings that may warrant further investigation and mitigation of vapor intrusion, as appropriate. VISLs are calculated for concentrations of volatile chemicals in groundwater, soil gas (exterior to buildings and sub-slab), and indoor air for default target risk levels and exposure scenarios. The VISL Calculator does not account for biodegradation so attenuation factors may need to be adjusted for biodegradable chemicals. The VISL Calculator draws on toxicity values from Regional Screening Levels (RSLs) for Chemical Contaminants at Superfund Sites, accessible at http://www.epa.gov/reg3hwmd/risk/human/rb-concentration_table/index.htm. Both the *VISL Calculator User's Guide* (EPA, 2014a) and *VISL Calculator* (EPA, 2014b) may be downloaded from EPA's web site: http://www.epa.gov/oswer/vaporintrusion/guidance.html. RSLs are drawn from a variety of sources according to EPA's three-tiered hierarchy of toxicity data (see "Human Health Toxicity Values in Superfund Risk Assessments" OSWER Directive 9285.7-53, 2003). Tier 1 (highest quality data) is EPA's Integrated Risk Information System (IRIS), accessible at http://www.epa.gov/iris/. Tier 2 are Provisional Peer Reviewed Toxicity Values (PPRTVs), accessible at http://hhpprtv.ornl.gov/ (also see EPA, 2009). Tier 3 include toxicity values from other sources such as the Agency for Toxic Substances and Disease Registry (ATSDR). Several states have also developed toxicity values, including California (CA DTSC, 2009), Hawai'i (HI DOH, 2008, 2012), Massachusetts (MA DEP, 2003), New Jersey (NJ DEP, 2013), and Washington (WA DEC, 2006). Links to these sources are provided under *References Cited* at the end of this section.

tertiary-butyl ether (MTBE) and tertiary-butyl alcohol (TBA), and the lead scavengers[14] ethylene dibromide (EDB), and 1,2-dichloroethane (1,2-DCA), plus other PHCs (e.g., naphthalene), may also pose a risk to human health. If present, their vapor intrusion potential should be assessed (see **Section 10**, p.81). The presence of biodegradable VOCs other than benzene may result in depletion of oxygen that is necessary for aerobic biodegradation of benzene, potentially resulting in farther migration of benzene vapors.

Phase Partitioning

When petroleum fuels are released into the subsurface from a leaking UST, PHCs may partition into several phases:

- Globules of light non-aqueous phase liquid (LNAPL) trapped within soil pore spaces (i.e., residual LNAPL)
- Dissolved in soil moisture
- Adhered onto the surface of, or absorbed into, soil solids
- Vapors in soil gas
- Accumulations of mobile LNAPL on and in the capillary fringe[15]
- Dissolved in groundwater

Low volume releases may result in contamination of only soil (including soil gas and soil moisture) and remain in the vadose zone. If the volume of a fuel release is sufficient, the fuel may accumulate on and in the capillary fringe and become mobile LNAPL. The mobile LNAPL generally spreads in the direction of groundwater flow, and may accumulate in monitoring wells. Temporal fluctuations in the elevation of the water table typically create a vertical smear zone of residual LNAPL contamination both above and below the average water table elevation. The more soluble components of the LNAPL mass dissolve into groundwater and are transported down gradient by the flowing groundwater as an aqueous phase. The remaining LNAPL mass will contain a sizeable fraction of aliphatic and relatively insoluble PHCs (e.g., naphthalene), especially if the source is large or unweathered (Lahvis, et al., 2013; EPA, 2013a). PHCs in the residual phase (both above and below the water table), the mobile phase (i.e., free product, LNAPL plume), and the dissolved phase (i.e., contaminant plume) all can serve as sources of PHC vapors. **Figure 2** illustrates the typical distribution of petroleum fuels in the subsurface resulting from a leaking UST. See **Section 2** (p.33) for a more detailed discussion of typical PVI scenarios.

---

[14] Older sites, where leaded gasoline was released to the subsurface, should be assessed for EDB and 1,2-DCA as they may represent a potential source of vapors (see **Section 10**). For more information about lead scavengers, see Appendix F in *Evaluation Of Empirical Data To Support Soil Vapor Intrusion Screening Criteria For Petroleum Hydrocarbon Compounds* (EPA, 2013) and EPA's Lead Scavengers web site at *http://www.epa.gov/oust/cat/leadscav.htm*.

[15] Mobile LNAPL is often referred to as free product, especially in older documents and 40 CFR 280.

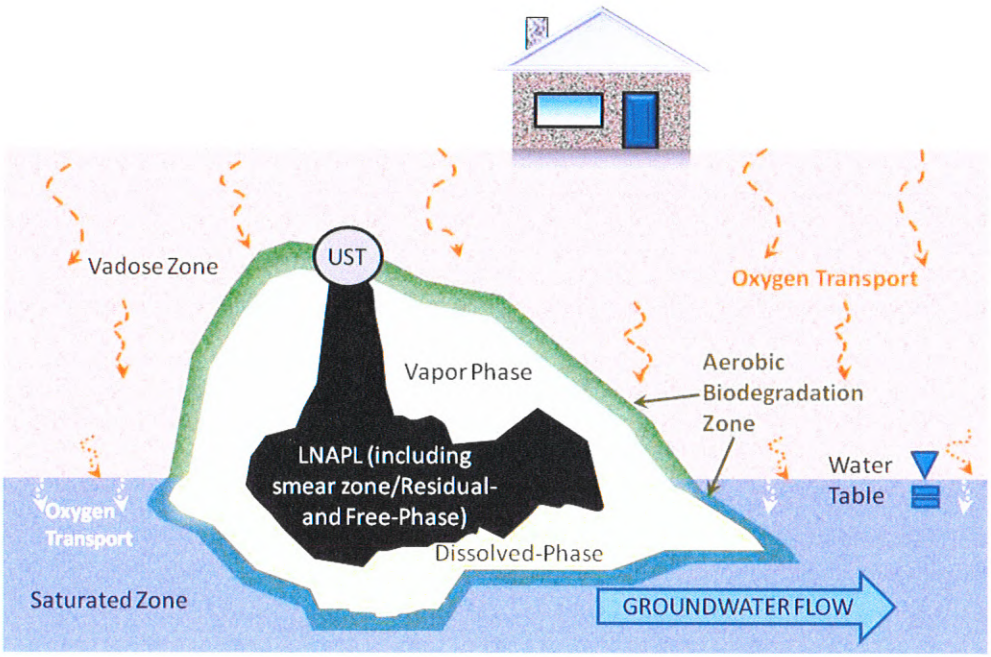

Figure 2. Conceptual Model Of Typical Petroleum Hydrocarbon Release

Aerobic biodegradation of PHCs along the perimeter of the vapor and dissolved plumes may limit the spread of subsurface contamination. Effective oxygen transport (dashed arrows) maintains aerobic conditions in the biodegradation zone. Petroleum LNAPL collects at the capillary fringe between the saturated and unsaturated zones (EPA, 2012).

Vapor Migration

Vapor migration results from two processes: diffusion and advection. Diffusion is the process whereby net transport of vapors from a source area of higher concentration (e.g., LNAPL, residual LNAPL, or dissolved plume) to an area of lower concentration occurs as a result of random molecular motion. Diffusion can also lead to chemical migration into buildings directly through a dirt floor or crawlspace, or through openings in the building slab and foundation such as passages for utility lines, sumps, and elevator pits. Also, intact concrete has appreciable permeability to diffusive gas movement (Kobayashi and Shuttoh, 1991; Sanjuan and Munoz-Martialay, 1996; and Tittarelli, 2009) and the permeability increases substantially when cracks are present (Daoud and Renken, 1999; EPA, 1995).

Advection refers to the movement of soil gas in response to pressure gradients. Advection can be an important mechanism for drawing soil gas and contaminant vapors through cracks in the basement floor or foundation into the building or back into the soil beneath the building. Heating and cooling systems can create differential pressures inside the building. When the pressure inside the building is lower than the pressure in the subsurface, vapors are drawn into the building. Conversely, when the pressure inside the building is greater than the pressure in

the subsurface, air within the building may be forced into the subsurface causing some degree of reoxygenation (Lundegard, Johnson, and Dahlen, 2008). Wind or changes in barometric pressure may also drive advective transport of oxygen into the subsurface beneath the building (Lundegard, Johnson, and Dahlen, 2008; Patterson and Davis, 2009; McHugh, DeBlanc, and Pokluda, 2006; Luo and Johnson, 2011; Robinson, Sextro, and Riley, 1997; Luo, et al., 2009; and Hong, Holton, and Johnson, 2012) (see **Section 11**).

Biodegradation Of PHCs

Biodegradation of PHCs is recognized as one of the primary mechanisms by which petroleum and other hydrocarbon pollutants are removed from the environment (Baedecker, Cozzarelli, and Hoppel, 1987; Leahy and Colwell, 1990). The biodegradability of PHCs often reduces the potential for human exposure from PVI (McHugh, et al., 2010; EPA, 2012; Interstate Technology & Regulatory Council [ITRC], 2014). Microorganisms are widely distributed in the environment and most are recognized as having some ability to metabolize PHCs (Gale, 1951; Ward, Singh, and Van Hamme, 2003; Prince, 2010). Although most microbes degrade a narrow range of organic compounds, they typically exist as a mixed consortium that collectively can biodegrade a wide range of organic compounds. Biodegradation progresses through stages with certain microbes being predominant until environmental conditions (e.g., availability of specific hydrocarbons, micronutrients, electron acceptors) become unfavorable for them at which time different microbes then become dominant (Wang and Deshusses, 2006; Suflita and Mormile, 1993; Corseuil, et al., 1998; Moyer, et al., 1996; Boopathy, 2004; Alexander, 1980; Prince, Parkerton, and Lee, 2007; Prince, 2010; and Bekins, et al., 2001). Thus, aerobic and anaerobic microbes may coexist with one class essentially dormant while the other is active.

Gasoline and diesel fuel (including biodiesel) may be completely biodegraded under aerobic conditions (Hult, 1987; Prince and Douglas, 2010; Prince, Parkerton, and Lee, 2007; Marchal, et al., 2003), though diesel fuel is more difficult and slower to biodegrade (Marchal, et al., 2003).[16] The end products of complete biodegradation (mineralization) of PHCs are water and carbon dioxide. Mineralization of PHCs is almost always the consequence of microbial activity (Alexander, 1981). If aerobic biodegradation of PHCs is incomplete, a variety of intermediate degradation products may be formed, but none of these are more toxic than the parent PHCs.

Aerobic biodegradation is well documented for many individual PHCs and classes of PHCs including:

- N-alkanes (Bouchard, et al., 2005; Prince, Parkerton, and Lee, 2007; Bailey, Jobson, and Rogers, 1973; Hult, 1989; Baedecker, et al., 2011)
- Branched alkanes (Prince and Douglas, 2010; Prince, Parkerton, and Lee, 2007); cycloalkanes (Bouchard, et al., 2005)

[16] The rate of aerobic biodegradation slows down with decreasing concentration of oxygen. Many aerobic microorganisms continue to function at concentrations as low as 0.1 mg/L of available oxygen, which is equivalent to an air concentration of 0.2%. For more information see research by Alagappan and Cowan (2004), Miralles-Wilhelm, Gelhar, and Kapoor (1997), and Mohamed, Saleh, and Sherif (2010).

- Aromatics (Wang and Deshusses, 2007; Phelps and Young, 1999; Landmeyer and Bradley, 2003; Lahvis, Baker, and Baehr, 2004; Lahvis, Baehr, and Baker, 1999; Bailey, Jobson, and Rogers, 1973; ZoBell, 1946; Corseuil, et al., 1998; Richnow et al., 2003)
- Naphthenes (Prince, Parketon, and Lee, 2007; Bailey, Jobson, and Rogers, 1973; Anderson, et al., 1999; ZoBell, 1946)
- Phenols (ZoBell, 1946; Basha, Rajendran, and Thangavelu, 2010)
- Trimethylbenzenes (Chen, et al., 2009)

Though aerobic biodegradation has been studied for over a century, anaerobic biodegradation of PHCs has been recognized only within the past three decades (Widdel, Boetius, and Rabus, 2006; Spormann and Widdel, 2000; and Townsend, et al., 2003). Anaerobic microorganisms degrade PHCs by using an electron acceptor other than oxygen (e.g., sulfate, nitrate, ferrous iron, or carbon dioxide). Anaerobic biodegradation is a slower process than aerobic biodegradation (Widdel, Boetius, and Rabus, 2006; Bailey, Jobson, and Rogers, 1973; and Lanham et al., 2013) and anaerobes grow slower than their aerobic counterparts (Widdel, Knittel, and Galushko, 2010). Instead of water and carbon dioxide, complete anaerobic biodegradation of PHCs (and naturally-occurring organic matter in soil, such as peat) can produce methane (Zengler, et al., 1999), especially with a release of an ethanol-blended gasoline (Jewell and Wilson, 2011; Ma, et al., 2012; Ma, et al., 2014). Incomplete anaerobic biodegradation of PHCs can produce compounds of higher toxicity, but these vapors are readily biodegraded in the vadose zone under aerobic conditions, and thus should not present a threat of vapor intrusion. Anaerobic biodegradation is typically the predominant mechanism of biodegradation in the source zone (Anderson and Lovley, 1997). Additional references documenting anaerobic biodegradation of PHCs are listed under *Additional Information* at the end of this section.

Importance

Important factors cited by Lahvis and Baehr (1996) and Suarez and Rifai (1999) as being influential for aerobic biodegradation of PHC vapors include:

- Vapor source hydrocarbon concentration, flux, and composition (including methane)
- Oxygen demand (i.e., the oxygen required to biodegrade the available hydrocarbons and any other organic matter present) and oxygen availability
- Soil type and properties (including texture and moisture content)
- Availability of essential micronutrients
- Ambient temperature in the subsurface
- The pH of the soil and groundwater

Additional factors cited by EPA (2012) as influencing the potential for PVI include:

- Size and characteristics of the building and adjacent land surface
- Distance between the vapor source and the building

Assessment

An assessment of the potential for PVI is not an isolated activity, but rather an integral part of the normal response to a suspected or confirmed release of PHCs from a leaking UST. At any leaking UST site (including abandoned sites or those that will be redeveloped for other uses), it is important to have a thorough understanding of the nature and magnitude of the release; the physical, biological, and chemical characteristics of the subsurface environment; an understanding of the preferential pathways for contaminant transport; and locations of receptors in the vicinity of the release. This is determined through collection and analysis of samples of soil, soil gas, groundwater, and sometimes LNAPL. Any other conditions (e.g., seasonal, weather-related; see **Section 11**, p.96) that may influence the transport of contaminants and potentially impact the safety and health of nearby building occupants should also be investigated.

Vapors emanating from dissolved-phase sources are primarily water soluble compounds, the more soluble aromatic hydrocarbons (e.g., BTEX) and other volatile and semi-volatile hydrocarbons and fuel additives (Lahvis, et al, 2013; EPA, 2013a). Vapors emanating from LNAPL sources contain a significantly larger fraction of aliphatic compounds and relatively insoluble hydrocarbons, especially if the source is large or unweathered (Lahvis, et al., 2013; EPA, 2012). Analyses of samples of soil, soil gas, groundwater, and LNAPL collected during site characterization (see **Section 3**, p.39) will provide information on specific contaminants that may warrant assessment for potential vapor intrusion.

Special Considerations

Several factors may preclude the effectiveness of aerobic biodegradation to mitigate the threat of vapor intrusion. They include:

- Source volume and composition (including PHCs and non-PHC fuel additives)
- Soil properties (moisture content, permeability, high organic carbon content, especially peat)
- Large building size
- Extensive impermeable surface covering (e.g., asphalt, concrete)
- Preferential transport pathways (including both natural and man-made)

If present, these factors may reduce the potential for biodegradation of PHC vapors and warrant additional investigative steps (e.g., collection of soil gas samples—see **Section 8**, p.66) to determine if the use of screening criteria (e.g., vertical separation distance) is appropriate.

The age and volume of release should be determined or estimated. When the release is relatively recent or if the volume of the release is relatively large[17], there is greater potential for PVI than for smaller or older releases, which may be more weathered. Large volume PHC

[17] The adjective *large* refers to either the total volume of the release or the areal extent (footprint) of the LNAPL mass in the subsurface.

releases may require a greater separation distance for biodegradation to be effective due to increased oxygen demand (EPA, 2013a).

Biodegradation of recent releases of high ethanol blended gasoline (i.e., E-20 or greater) may consume oxygen that would otherwise be available for biodegradation of PHCs resulting in an increased potential for PVI (Ma et al., 2014). In addition, the biodegradation of ethanol may result in the advective transport of methane and a potential risk of explosion. Thus, larger separation distances may be necessary to mitigate the threat of explosion or PVI at sites where high ethanol blended fuel has been released into the subsurface (Ma et al., 2014).

Preferential transport pathways may be either natural (e.g., fractures in rock, solution channels in karst terrain, bedding planes, joints, high permeability layers) or man-made (e.g., utility corridors including sewer lines themselves, trenches, excavations). Because they increase the speed at which the contaminants move through the subsurface, preferential transport pathways can potentially short circuit protectiveness that would otherwise be provided by biodegradation of PHCs and other fuel additives in homogeneous soils. Typically, it is difficult to detect and map natural preferential transport pathways, and contamination may present itself in unexpected locations. Local government offices have maps of utility corridors that can provide information on the presence and location of man-made preferential transport pathways.[18]

Recommended Steps For Addressing The Potential Risk From PVI

EPA recommends the following actions for situations in which EPA, state, tribal, and local agencies are investigating releases of petroleum-based fuels (including addressing potential risks due to PVI) at leaking UST sites or where 40 CFR 280 requires[19] UST owners and operators to undertake release investigation and corrective action activities:

- ✓ ***Assess and mitigate immediate threats to safety***

Some releases from UST systems are discovered through noticeable sensory indicators on neighboring properties. Indicators may include sight, smell, taste, or physiological effects (e.g., dizziness, headache, nausea, vomiting, and confusion). The presence of odors does not necessarily correspond to adverse health or safety impacts from PVI, as the odors could be the result of indoor vapor sources. However, it is generally prudent to investigate any reports of odors in close proximity to UST systems as the odor threshold for some chemicals exceeds their acceptable health-based concentrations. PHC odors are a nuisance and may trigger the need

[18] A federally mandated national call center was established to ensure that utility lines are marked before digging or boring. Dial 811 to have the locations of utilities marked before conducting site work that involves digging or boring. For more information, visit http://www.call811.com/default.aspx

[19] In the case of a suspected or confirmed release from a regulated UST system, Subparts E and F of 40 CFR 280 require owners and operators to investigate, report, and perform corrective action (including recovery of LNAPL to the maximum extent practicable) if contamination is present, and submit timely reports of activities and findings to the implementing agency.

for abatement or mitigation even if the concentration in indoor air is below acute or chronic health-based levels.

In confined spaces, the presence of flammable PHC vapors and non-PHC fuel additive vapors or methane may pose a threat of fire or explosion and endanger building occupants. Federal regulations (40 CFR 280.61) require that immediate action be taken to prevent any further release of the regulated substance into the environment and that fire, explosion, and vapor hazards be identified and mitigated (*Federal Register*, 1988). Section 280.64 requires that free product (mobile LNAPL) be recovered to the maximum extent practicable and that records be kept of the volumes recovered. First responders, typically fire department personnel, should be notified if there are reports of either odor from petroleum or the presence of an oily sheen on basement floors or in sumps, drains, or elevator pits. It may be necessary to evacuate building occupants until the threat from fire or explosion has been mitigated. Since methane is odorless and colorless, monitoring devices are required if methane is suspected.

✓ ***Conduct a site characterization and develop a conceptual site model (CSM)***

Once the immediate threats to safety have been mitigated (or it is determined that immediate threats do not exist), determine whether there is a long-term threat to human health and the environment from intrusion of petroleum vapors. Site characterization[20] and CSM development provide information about the full extent and location of the contamination; the nature and characteristics of the contamination; the characteristics of the site that influence contaminant migration, including the potential for biodegradation of PHCs; and the locations of receptors. Information derived from the CSM helps ensure that sources, pathways, and receptors throughout the site are considered; this knowledge can lead to selection of the most appropriate sampling locations and techniques. A systematic soil gas sampling program may also aid in defining the full extent and location of contamination, detecting the presence of preferential transport pathways, and locating pockets of PHC vapors. Preferential transport pathways are avenues of least resistance to the migration of contaminants whether in the dissolved phase, LNAPL phase, or vapor phase. They include both natural and man-made features such as:

Natural

- gravel lenses and channels
- solution channels in karst terrain
- bedding planes
- fractures, joints, and faults in consolidated rock

Man-made

- utility corridors (including sewer lines themselves) and trenches
- elevator pits
- sumps and drainage pits
- other types of excavations

[20]The term *site characterization* is used throughout this document for consistency. *Site characterization* is often used interchangeably with *site assessment*, *site evaluation*, *site investigation*, and sometimes *site check* as they all mean assembling and collecting information and data about a site.

Preferential transport pathways increase the speed at which contamination moves through the subsurface such that contaminants may not biodegrade by the time they reach receptors. They can also allow atypical movement, which in some cases may be opposite groundwater flow (ITRC, 2014). Because preferential transport pathways can short-circuit the protectiveness provided by lateral and vertical separation distances described in this PVI guide, indoor air sampling is recommended in situations where they connect vapor sources and receptors. See **Section 3** (p.39) for more information about site characterization and CSMs.

✓ ***Delineate a lateral inclusion zone***

Based on the CSM, delineate a lateral inclusion zone. The lateral inclusion zone is the area surrounding a contaminant mass through which petroleum vapors may travel, intrude into buildings, and potentially pose a threat to human health and the environment. Buildings directly above contamination sources, whether as mobile LNAPL, residual LNAPL, or PHCs dissolved in groundwater, are considered within the lateral inclusion zone. Buildings outside this zone generally may be excluded from further assessment for PVI unless:

- Site conditions change (e.g., groundwater flow direction changes, contaminant plume migrates beyond the lateral inclusion zone, development or redevelopment of nearby properties)
- Preferential transport pathways are present

In such instances, additional investigation may be warranted to more fully evaluate the risk from PVI. See **Section 4** (p.44) for more information on delineating a lateral inclusion zone.

✓ ***Determine vertical separation distances***

The vertical separation distance is the thickness of clean, biologically active soil (see **Section 9**, p.75) between a contaminant mass and the lowest point of an overlying receptor (e.g., building basement floor, foundation, or crawl space surface). Consolidated rock is not soil and should not be included in the vertical separation distance. For example, for a situation in which there is 3 feet of soil above fractured rock and the depth to contaminated groundwater is 7 feet, the vertical separation distance is 3 feet, not 7 feet. Some buildings within the lateral inclusion zone will overlie PHC contamination that exists as either a mobile LNAPL mass, residual soil contamination (including the smear zone), or dissolved in a groundwater plume. However, not all of these buildings will be threatened by PVI due to aerobic biodegradation of PHCs provided there is sufficient vertical separation distance between the receptor and the vapor source. The vertical separation distance between contamination and overlying buildings is determined as part of the normal site characterization process. The full extent and location of contaminant sources should have been adequately mapped in the subsurface and the nature and characteristics of the contamination should have been determined during site characterization and conceptual site model development (see **Section 3**, p.39).

EPA (2013a) presents analysis of petroleum vapor source data and soil gas data from a number of leaking UST sites across the United States. The report findings support screening criteria for dissolved and LNAPL PHC releases from leaking USTs. For dissolved PHC sources that are separated from overlying buildings by more than 6 feet of clean, biologically active soil, the potential threat of PVI is negligible and further investigation for PVI is generally unnecessary. For LNAPL sources that are separated from overlying buildings by more than 15 feet of clean, biologically active soil, the potential threat of PVI is negligible and further investigation for PVI is generally unnecessary. These separation distances are believed to be sufficiently protective in most situations because they include a number of built-in safety factors, which are discussed in more detail in **Section 5** (p.48). If the distance separating the source of PHC vapors and overlying buildings is less than 6 feet for dissolved sources and 15 feet for LNAPL sources, additional investigation is recommended.

EPA (2013a) recognizes that there are a number of precluding factors that may justify a greater vertical separation distance in some cases. These factors include:

- Influence of methanogenesis on oxygen demand (especially for higher ethanol blends of gasoline)
- Effect of extensive high organic matter content soils (e.g., peat) with potentially high natural oxygen demand
- Reduced oxygen flux caused by certain geologic conditions (e.g., low permeability surface layer overlying coarse-grained soils, soil moisture from precipitation (Luo et al., 2009))
- Limited knowledge of vapor attenuation behavior in fractured rock
- Limited soil gas data for non-UST (e.g., petroleum refinery, fuel terminal) sites
- Limited data on vapor attenuation behavior of aliphatic compounds
- Lack of soil vapor data for the lead scavengers ethylene dibromide (EDB) and 1,2-dichloroethane (1,2-DCA) (see **Section 10**, p.81, for more information on these contaminants)

Other site characteristics that may warrant additional investigation include exceptionally dry soils (<2 percent soil moisture), areas covered by extensive impervious paving or large buildings, and presence of preferential transport pathways (see **Section 3**, p.39). Also, soil gas movement may vary seasonally in response to differential pressures created by heating and cooling of overlying buildings (see **Section 11**, p.96).

✓ ***Evaluate vapor source and attenuation of PHC vapors***

Where contamination is not in direct contact with an overlying building, EPA recommends one of two options: (1) collection of near-slab (exterior) shallow soil gas samples paired with deep (near source) soil gas samples, or (2) collection of indoor air samples paired with sub-slab soil

gas samples to evaluate attenuation of PHC vapors and the potential for PVI.[21] When collecting soil gas samples[22], use option 1 under the following conditions (EPA, 2013b):

- A building, with the shortest side no longer than 66 feet, overlies LNAPL and the vertical separation distance is less than 15 feet, but not in direct contact with the building basement floor, foundation, or crawl space surface.
- A building, of any dimension, overlies dissolved PHC contamination and the vertical separation distance is less than 6 feet, but not in direct contact with the building basement floor, foundation, or crawl space surface.

Use option 2 for buildings larger than 66 feet on a side or if near-slab soil gas samples from around smaller buildings do not clearly demonstrate that biodegradation is sufficient to mitigate the threat of PVI by reducing PHC concentrations to below applicable human health thresholds (see Footnote #13).

The purpose of collecting paired samples is to enable determination of a building-specific vapor intrusion attenuation factor. Generic attenuation factors that do not account for biodegradation of PHCs are conservative and, likely overestimate the transfer of contaminants from soil gas to indoor air in most buildings. Attenuation factors (see **Section 12**, p.100) that account for biodegradation can be derived from models such as *BioVapor* or *PVIScreen* (see **Section 13**, p.106). Additional information may be found in Wilson *et al.* (2014).

If contamination (either dissolved, or LNAPL whether mobile or residual) is in direct contact with a building basement floor, foundation, or crawlspace surface, EPA recommends indoor air sampling (these samples cannot be paired with subsurface soil gas samples because there is no clean, biologically active soil between the contamination and the building). Information on collecting and analyzing sub-slab vapor samples and indoor air samples is beyond the scope of this document, but is provided in other documents, for example ITRC (2014) and EPA (2015).

Indoor air in many buildings will contain detectable levels of a number of vapor-forming compounds whether or not the building overlies a subsurface source of vapors, because indoor air can be impacted by a variety of indoor and outdoor sources. The composition of outdoor air surrounding a building is referred to as ambient air throughout this document. The combined contribution of indoor and outdoor sources of vapors to indoor air concentrations is referred to as background throughout this document. To differentiate and quantify the relative contribution of contaminants from PVI versus background sources, indoor air samples must be collected in conjunction with sub-slab (or near-slab, as appropriate) soil gas samples. ITRC

---

[21] Implementing authorities may opt for sub-slab soil gas and indoor air sampling in any situation they deem necessary to protect the safety and health of building occupants.

[22] Soil gas samples should be analyzed for oxygen, carbon dioxide, PHCs (and any other fuel constituents likely to be present including fuel additives), and methane. As a quality assurance/quality control check, nitrogen can be added to the analyte list at a nominal cost. This will enable determination of whether significant concentrations of other gases are unaccounted for as these gases should account for nearly 100 percent of the total present. (See **Section 8**).

(2014) and EPA (2015) provide information on background sources, techniques, and methods to account for background contributions to indoor air concentrations.

Information on historic concentrations of background vapors is presented in *Background Indoor Air Concentrations of Volatile Organic Compounds in North American Residences (1990 – 2005): A Compilation of Statistics for Assessing Vapor Intrusion* (EPA, 2011b). In addition, the Montana Department of Environmental Quality (MT DEQ, 2012) conducted an extensive investigation of the indoor air quality of typical uncontaminated buildings in Montana. The objective of these studies is to illustrate the ranges and variability of VOC concentrations in indoor air resulting from sources other than vapor intrusion. While these studies provide expected ranges of indoor air contaminants, EPA recommends building-specific sampling (rather than using literature values) to characterize actual contaminant levels. If measured indoor air concentrations are found to greatly exceed the historic range of background levels, there is a greater likelihood that the indoor air concentrations are the result of vapor intrusion. Studies such as EPA (2011) and MT DEQ (2012) can be employed to determine whether measured indoor air concentrations exceed the historic range of background concentrations.

If the attenuation factor calculated from results of analysis of the chosen pair or vapor samples indicates that there may be a potential for PVI above applicable exposure limits, EPA recommends additional investigation to determine whether mitigation is appropriate.

✓ ***Mitigate petroleum vapor intrusion, as appropriate***

If contaminant concentrations represent a potential threat of fire or explosion (i.e., vapor concentrations are more than 10% of the lower explosive limit), or indoor air sampling indicates that PVI is occurring, EPA recommends that active mitigation measures be immediately initiated. ITRC (2014) and EPA (2015) provide information on mitigation and remediation of vapor intrusion. In addition, the source of contamination should be remediated per Subpart F of the Federal Regulations (40 CFR 280.60 through 280.67) (Federal Register, 1988). In particular, 40 CFR 280.64 requires the recovery of LNAPL to the "maximum extent practicable".

See the following sections for more information on the factors discussed in the paragraphs above:

2. Typical PVI Scenarios

Description

The potential for PVI is primarily a function of the location of the contamination source relative to a potential receptor, source volume and strength, and the source mass distribution in the subsurface. Source concentrations are typically much higher for LNAPL sources than for dissolved-phase sources. Higher source concentrations will generate higher rates of mass diffusion (flux). The higher mass flux will also be more sustained over time because LNAPL sources will contain significantly more mass compared to dissolved-phase sources. Oxygen demand and the potential for encountering anaerobic conditions are also uniquely different between LNAPL and dissolved-phase sources. For both dissolved and LNAPL sources, the biodegradation reaction front is relatively narrow, but it occurs higher in the unsaturated zone (closer to land surface) over an LNAPL source than it does over a dissolved-phase source (**Figure 3**).

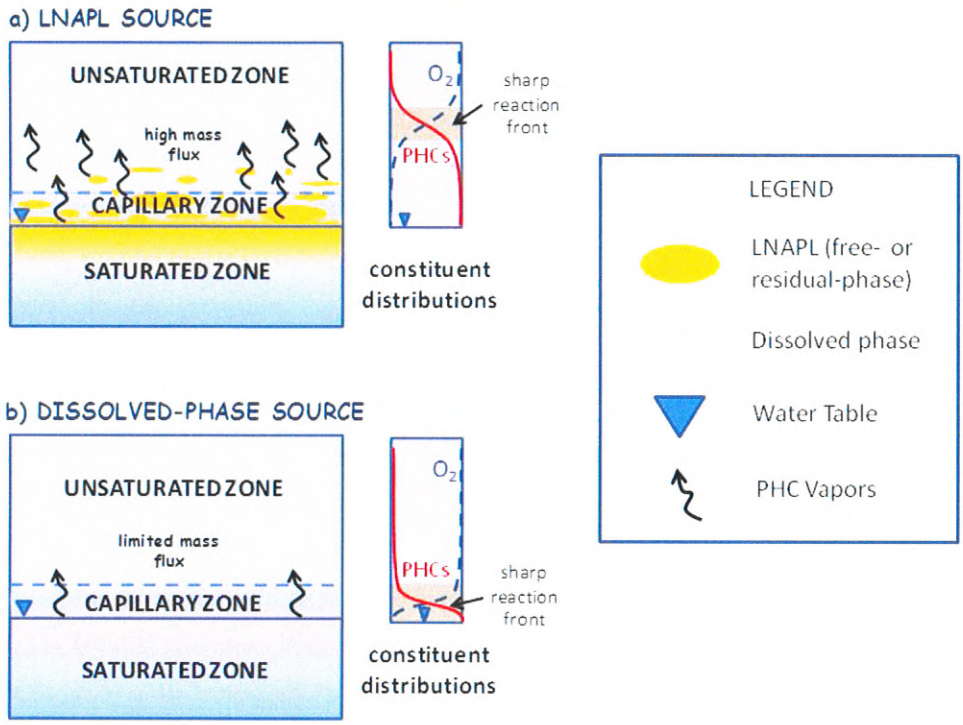

Figure 3. Difference In Potential For PVI Based On Type Of Source: a) LNAPL, b) Dissolved Phase (Source: Lahvis, et al., 2013. Reprinted from *Groundwater Monitoring & Remediation* with permission of the National Ground Water Association. Copyright 2013.)

LNAPL sources may be distributed both above and below the capillary fringe as a result of smearing from water-table fluctuations. This phenomenon will tend to enhance mass flux to the unsaturated zone because of direct partitioning between LNAPL (residual) and vapor phases. Conversely, the mass flux will be more limited for dissolved-phase sources because vapor transport through water is reduced relative to diffusion in soil gas (Golder Associates, 2006; Lahvis and Baehr, 1996). Vapor diffusion is limited by low effective air-phase porosity (i.e., high moisture saturation) and biodegradation in the capillary zone.

Importance

Relatively few confirmed occurrences of PVI at petroleum sites are reported in the literature (EPA, 2013, Section 2.6, p.9). The most likely scenarios for PVI to occur are shallow PHC sources directly beneath buildings and mobile LNAPL or groundwater plumes with high concentrations of PHCs that are in direct contact with buildings (Davis, 2009; and McHugh, et al., 2010). A study by Peargin and Kolhatkar (2011) suggests that a dissolved source with benzene greater than 1 mg/L may behave like a LNAPL source in terms of vapor-generating capability.

Assessment

Recommended steps for investigating PVI are discussed in **Section 1** (p.11). Application of the screening criteria allow for the determination of which buildings are threatened by PVI. Using this approach, resources can be appropriately focused on those buildings potentially impacted by PVI.

Figure 4 presents typical scenarios of the spatial relationship between PHC sources and potential receptors. However, it is not intended to be a comprehensive depiction of all possible configurations of such a relationship.

Table 2 summarizes the characteristics of these six scenarios relative to lateral and vertical distances from contamination and necessary investigation activities.

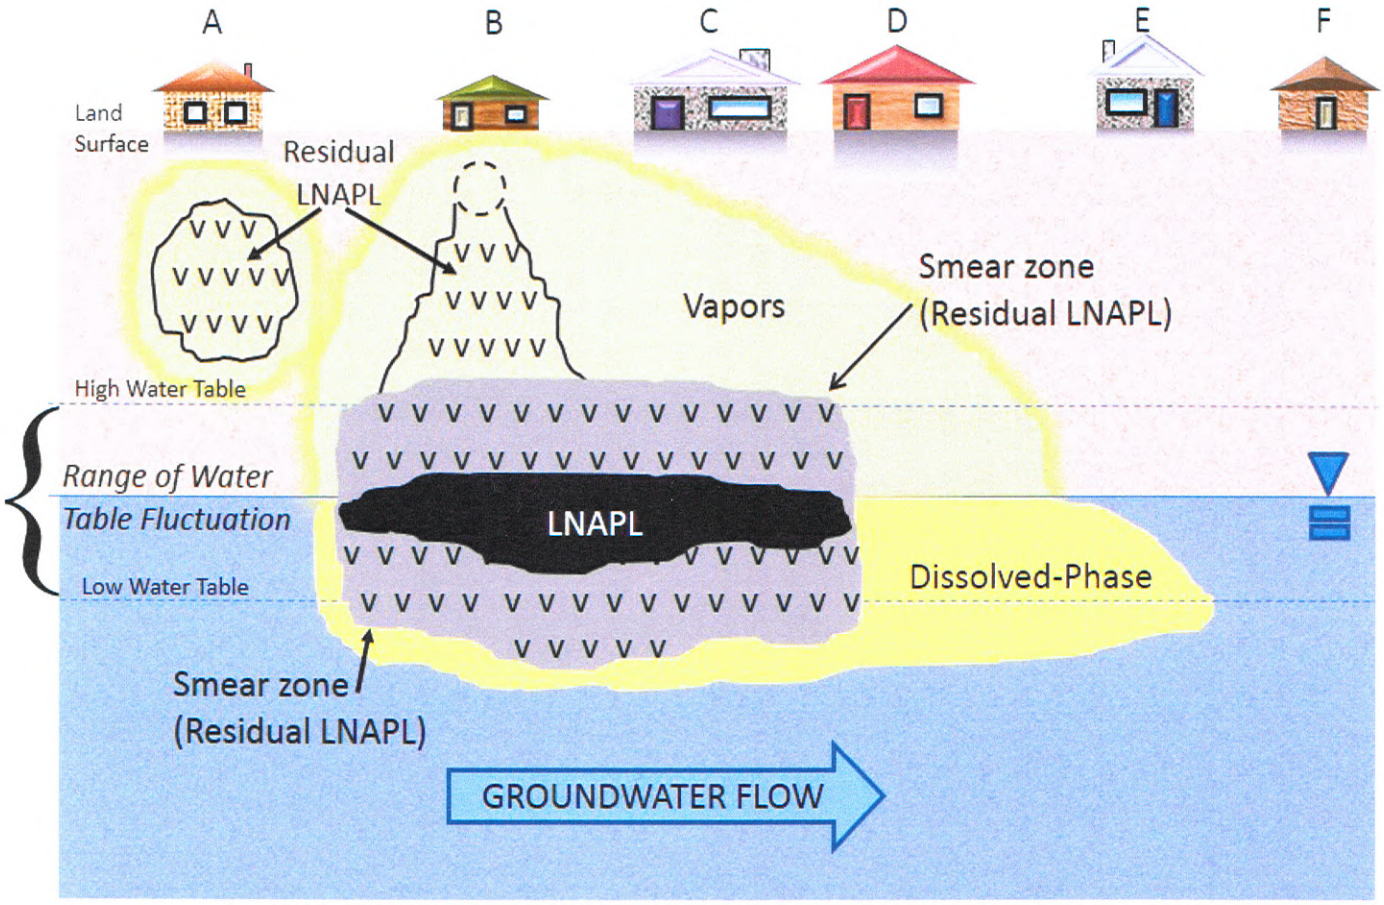

Figure 4. Typical Scenarios Of Potential PVI Sources And Potential Receptors

Table 2. Summary Of Characteristics Of Typical Scenarios Of Petroleum Vapor Sources And Potential Receptors.

Scenario (as illustrated in Figure 4)	Contamination Beneath Building? (building is within lateral inclusion zone)	Potential For PVI	Near-Slab* Soil Gas Sampling Recommended?
A	Yes; shallow residual LNAPL in the vadose zone	High	Yes, if vertical separation distance is less than 15 feet from the top of residual LNAPL, otherwise No
B	Yes; residual including smear zone, LNAPL, dissolved in groundwater	High	Yes, if vertical separation distance is less than 15 feet from the top of the smear zone, otherwise No
C	Yes; smear zone, LNAPL, dissolved in groundwater	Medium	Yes, if vertical separation distance is less than 15 feet from the top of the smear zone, otherwise No
D	Yes; dissolved in groundwater	Low	Yes, if vertical separation distance is less than 6 feet from the historical high water table elevation, otherwise No
E	Maybe; plume may be diving beneath water table	Low – None	Yes, if vertical separation distance is less than 6 feet from the historical high water table elevation, otherwise No
F	No	None	No

*Near-slab soil gas samples should be collected from each side of the potentially impacted building and as close to the building as possible. These samples should be paired with deep (near source) soil gas samples. If these samples do not clearly demonstrate that biodegradation is sufficient to mitigate the threat of PVI into the building, EPA recommends collection of indoor air samples paired with sub-slab soil gas samples.

Special Considerations

While biodegradation may reduce the potential for human exposure to petroleum vapors, its effectiveness in mitigating PVI may be limited by precluding factors such as:

- Migration of contaminants, especially plumes in flowing groundwater
- Presence of non-PHC chemicals that biodegrade too slowly (or the rate is not known with certainty)
- Presence of preferential transport pathways
- Extensive impermeable surface cover, or very large buildings
- Presence of higher blends of ethanol in gasoline that consumes oxygen that would otherwise be available for aerobic biodegradation of PHCs
- Generation of methane from higher blends of ethanol in gasoline that exerts high oxygen demand and presents a vapor intrusion threat itself
- Soils with high organic content (e.g., peat) that exert a high oxygen demand
- Soil conditions that are inhospitable to microorganisms such as insufficient soil moisture
- Insufficient thickness of clean, biologically active soil
- LNAPL source is relatively unweathered and rich in volatile PHCs

Recommendation

EPA recommends conducting an adequate PVI investigation and following the steps described in **Section 1** (p.11) to determine which buildings may be at risk for PVI.

3. Site Characterization And Conceptual Site Model (CSM)

Description

Site characterization is the process by which site-specific information and data are gathered from a variety of sources to characterize the physical, biological, and chemical systems at a contaminated site. A conceptual site model (CSM) integrates all data and information into a three-dimensional picture of site conditions that illustrates contaminant distributions, release mechanisms, migration routes, exposure pathways, and potential receptors (EPA, 2012; ITRC, 2014). The CSM uses a combination of text and graphics to portray both known and hypothetical information (EPA, 2011). The CSM documents current conditions at the site and is supported by maps, cross-sections, and site diagrams. The CSM illustrates potential human and environmental exposure through contaminant release and migration toward receptors (EPA, 1995, 1996a). The CSM should be refined as new data are collected.

Importance

At any leaking UST site, it is important to have a thorough understanding of the full extent and location of contamination (including both PHCs and non-PHC fuel additives), the characteristics of the site that influence contaminant migration (especially the presence of preferential transport pathways), and the locations of potential receptors. A CSM helps ensure that sources, pathways, and receptors throughout the site have been considered; this knowledge can lead to selection of the most appropriate sampling locations and techniques. The CSM assists the site manager in evaluating the interaction of different site features. Risk assessors use conceptual models to help plan for risk assessment activities (EPA, 1995). The CSM is the basis for making informed risk management decisions about the site and the threat posed by PVI to nearby buildings and their occupants. In addition, remedial action costs are influenced by the quality of the CSM (EPA, 1996b).

Assessment

An investigation for PVI potential is not separate from the normal response to a confirmed UST release; an adequate site characterization is essential in order to construct an accurate CSM. A primary objective of site characterization is delineation of the aerial and vertical extent of contamination in the subsurface (per 40 CFR 280.65(a)) so that lateral and vertical separation distances can be accurately determined.[23] It is also important to determine whether preferential transport pathways are present and, if so, delineate them to determine if they connect vapor sources directly to potential receptors. Site characterization generally proceeds in a systematic manner, often beginning in or near the source area and working outward and in the downgradient direction in which groundwater flows.

---

[23] The separation distances described in this document (**Section 5**, Table 3, p.52) and the protectiveness provided by clean, biologically active soil against vapor intrusion by PHCs may be insufficient to protect against vapor intrusion by non-PHC fuel additives. Additional investigation should be conducted where certain additives are present (see **Section 10**, p.81).

All information and data about the site should be integrated into a CSM, which is continually updated and refined to account for changing conditions and new information. Basic activities associated with developing a CSM include:

- Identification of potential contaminants[24]
- Identification and characterization of the source of contaminants
- Characterization of the geochemical parameters that affect biodegradation
- Characterization of the geologic and hydrogeologic characteristics of the subsurface
- Delineation of potential migration pathways, including preferential transport pathways, through environmental media
- Establishment of background levels of contaminants and areas of contamination for each contaminated medium
- Identification and characterization of potential receptors
- Determination of the limits of the study area or system boundaries

Tracking contaminant migration from sources to receptors is one of the most important uses of the CSM (ASTM, 2008). Uncertainties associated with the CSM should also be identified as well as the efforts taken to reduce uncertainties to acceptable levels (ASTM, 2008). As new information and data become available, the CSM should continually be refined (EPA, 1993; ITRC, 2007). ITRC (2014), EPA (2013, 2015), and Wilson et al., (2014) provide additional information about developing CSMs.

Special Considerations

The separation distances described in this document (**Section 5**, Table 3, p.52) and the protectiveness provided by clean, biologically active soil against vapor intrusion by PHCs may be insufficient to protect against vapor intrusion by non-PHC fuel additives. Additional investigation should be conducted where certain additives are present (see **Section 10**, p.81).

The presence and locations of preferential transport pathways should be identified and incorporated into the CSM. All new information and data about a site, including potential future land uses, should also be identified to refine the CSM.

Recommendation

Per Subparts E and F in 40 CFR 280.50 through 280.67 (see *http://www.epa.gov/oust/fedlaws/cfr.htm*), EPA recommends that an adequate site characterization considers the following:

- §280.52(b) Release Investigation and Confirmation Steps:

"Owners and operators must measure for the presence of a release where contamination is most likely to be present at the UST site. In selecting sample types, sample locations, and measurement methods, owners and operators must consider the nature of the stored

[24] The list of potential contaminants should include BTEX and other PHCs as well as non-PHC fuel additives likely to have been present in the fuel stored at the site. See **Section1** (p.11) and **Section 10** (p.81) for more information.

substance, the type of initial alarm or cause for suspicion, the type of backfill, the depth of ground water, and other factors appropriate for identifying the presence and source of the release."

- §280.62(a)(5) Initial Abatement Measures and Site Checks

"Measure for the presence of a release where contamination is most likely to be present at the UST site, unless the presence and source of the release have been confirmed in accordance with the site check required by §280.52(b) or the closure site assessment of §280.72(a). In selecting sample types, sample locations, and measurement methods, the owner and operator must consider the nature of the stored substance, the type of backfill, depth to ground water and other factors as appropriate for identifying the presence and source of the release. . ."

- §280.63(a)(1-4) Initial Site Characterization

". . .owners and operators must assemble information about the site and nature of the release, including information gained while confirming the release or completing the initial abatement measures. . . This information must include, but is not necessarily limited to the following: (1) Data on the nature and estimated quantity of release; (2) Data from available sources or site investigations concerning the following factors: surrounding populations, water quality, use and approximate locations of wells potentially affected by the release, subsurface soil conditions, locations of subsurface sewers, climatological conditions, and land use; (3) Results of the site check required under §280.62(a)(5); and (4) Results of the free product investigations. . ."

- §280.64 Free product removal

"At sites where investigations under §280.62(a)(6) indicate the presence of free product, owners and operators must remove free product to the maximum extent practicable as determined by the implementing agency while continuing, as necessary, any actions initiated under §§280.61 through 280.63, or preparing for actions required under §§280.65 through 280.66. In meeting the requirements of this section, owners and operators must: . . . (d) Unless directed to do otherwise by the implementing agency, prepare and submit to the implementing agency, within 45 days after confirming a release, a free product removal report that provides at least the following information: . . . (2) The estimated quantity, type, and thickness of free product observed or measured in wells, boreholes, and excavations;"

- §280.65(a) Investigation for soil and ground water cleanup

"In order to determine the full extent and location of soils contaminated by the release and the presence and concentrations of dissolved product contamination in the groundwater, owners and operators must conduct investigations of the release, the release site, and the surrounding area possibly affected by the release. . ."

- §280.66(b)(1-6) Corrective Action Plan

"In making this determination, the implementing agency should consider the following factors as appropriate: (1) The physical and chemical characteristics of the regulated

substance, including its toxicity, persistence, and potential for migration; (2) The hydrogeologic characteristics of the facility and the surrounding area; (3) The proximity, quality and current and future uses of nearby surface water and ground water; (4) The potential effects of residual contamination on nearby surface water and ground water; (5) An exposure assessment; and (6) Any information assembled in compliance with this subpart."

4. Lateral Inclusion Zone

Description

The lateral inclusion zone is the area surrounding a contaminant source through which vapor-phase contamination may travel and intrude into buildings. Determination of the lateral distance within which buildings and other structures may be threatened by PVI is site-specific. In general, with increasing confidence in the site characterization and the CSM, there can be a corresponding decrease in the distance the lateral inclusion zone extends from clean monitoring points.[25] All buildings within the lateral inclusion zone should be further assessed to determine if they are separated from vapor sources by an adequate vertical separation distance (see **Section 5**, p.48). Further assessment may be unnecessary for those buildings outside the lateral inclusion zone unless preferential transport pathways are present. If contaminated groundwater is the source of vapors, migration of the contaminant plume (in the longitudinal, transverse, and vertical directions) should be assessed when evaluating the potential for future risks.

Importance

The lateral inclusion zone is a screening criterion to help determine which sites should definitely be assessed further for PVI; which sites might need additional site characterization and assessment for PVI; and which sites can reliably be excluded from consideration for further evaluation of PVI. All buildings that overlie, or are reasonably expected to overlie, contamination, whether LNAPL or the dissolved phase, are considered to be within the lateral inclusion zone.

Assessment

Lateral separation distance is schematically depicted in **Figure 5**. Though in theory the length of the lateral separation distance may be on the same scale as the vertical separation distance (EPA, 2013a; ITRC, 2014), a greater lateral distance is generally warranted in the down gradient direction (Lahvis, et al, 2013; EPA, 2013a). This is because the lateral boundaries of a migrating plume are more difficult to accurately delineate, as they are not stationary. Groundwater elevations fluctuate which may result in changes in the direction and velocity of groundwater flow. The lateral and down gradient investigation should continue until the full extent and location of contamination is determined. This is typically achieved by surrounding the dissolved-phase plume with clean monitoring points.

Both mobile LNAPL and dissolved contaminant plumes are dynamic and may move from one monitoring event to the next. As discussed in **Section 7** (p.61), periodic monitoring of groundwater flow directions and plume migration should be conducted, possibly over more than one annual cycle.

---

[25] A *monitoring point* is defined as a sampling point at which soil and groundwater samples are collected (typically from monitoring wells, though not exclusively) and which define the full extent and location of contamination. A *clean monitoring point* is defined by dissolved benzene concentration less than 5 µg/L and soil TPH concentration less than 20 mg/Kg.

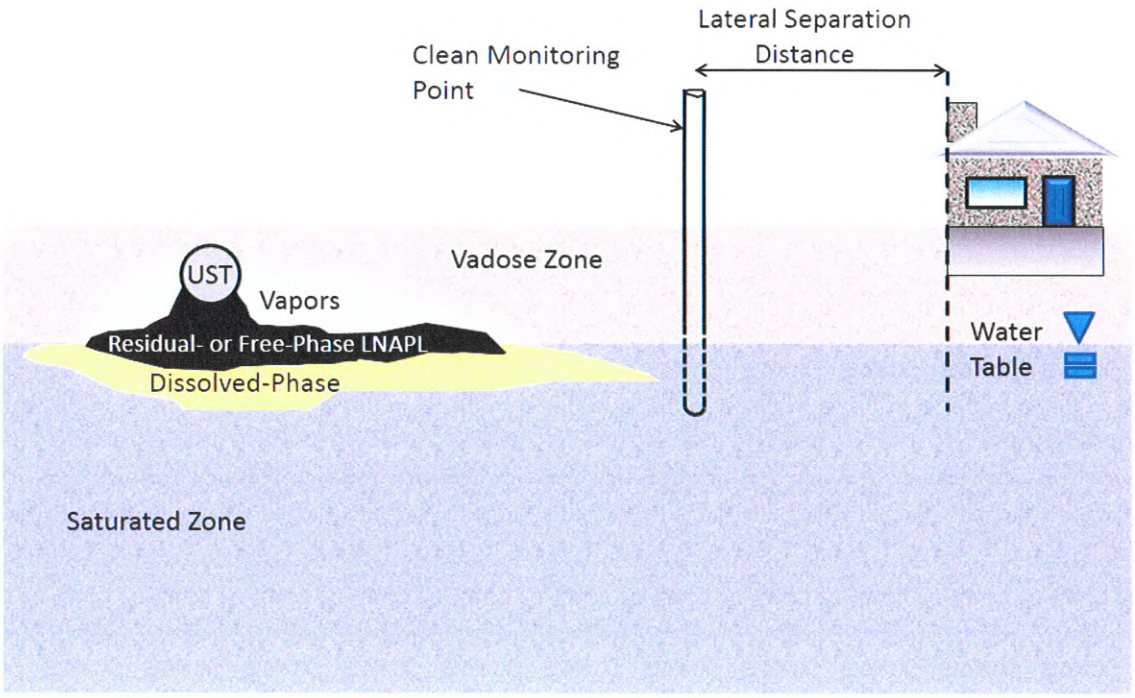

Figure 5. Lateral Separation Distance Between Source Of PHC Contamination And Hypothetical Receptor

Special Considerations

It can be difficult to accurately determine the exact location of contamination relative to potential receptors. This is in part due to the dynamic nature of contaminant plumes (both LNAPL and dissolved PHCs); the presence of heterogeneities and preferential transport pathways in geologic material; and the distance between monitoring points, such as soil borings and monitoring wells. It may be necessary to assess some nearby buildings for PVI before all site characterization activities have been completed.

It is important to consider whether, and what type of preferential transport pathways are present and could facilitate the migration of petroleum vapors. The presence of preferential transport pathways may circumvent the protectiveness that a sufficiently thick layer of clean, biologically active soil would otherwise provide. Preferential transport pathways such as utility conduits typically enter buildings through holes in the foundation or slab and can facilitate the entry of PHC vapors into the building. For example, if the transport of vapors from the source

area to the building could occur along utility conduits, then vapor sampling inside those utility conduits (e.g., sewers) should be considered. Field instrument screening at utility access points may help determine if the utility is acting as a conduit for vapors. Although specific guidance for utility sampling is beyond the scope of this document, EPA recommends that any utility sampling program include safety precautions to protect personnel (e.g., oxygen and combustible gas monitoring, confined-space entry requirements) and to avoid damage to utilities. For guidance on utility sampling, see *A Practical Strategy for Assessing the Subsurface Vapor-to-Indoor Air Migration Pathway at Petroleum Hydrocarbon Sites* (API, 2005).

Lateral separation distances that are usually protective against PVI may not be sufficiently protective in situations where methane is produced in large quantity, such as sites where high-ethanol blends of gasoline (i.e., E-20 or greater) have been released (Ma et al., 2014), and at sites where non-PHC fuel additives are present (see **Section 10**, p.81). In both of these cases, additional investigation should be conducted to assess the potential for vapor intrusion.

Another consideration is changing site conditions. Factors to consider in deciding whether to include sites for further evaluation of PVI may include future land use—that is, whether: future new buildings will be constructed within the lateral inclusion zone, utility trenches will be excavated through or near previous contamination, groundwater usage will potentially be increased, and additional releases of contaminants may occur.

Recommendation

Delineation of a lateral inclusion zone is site-specific. EPA recently published *An Approach for Developing Site-Specific Lateral and Vertical Inclusion Zones within which Structures Should be Evaluated for Petroleum Vapor Intrusion due to Releases of Motor Fuel from Underground Storage Tanks (EPA, 2013b)*. This Issue Paper describes a procedure for constructing a lateral inclusion zone that decision makers may find useful. EPA recommends that all buildings within the lateral inclusion zone be further assessed to determine if they are separated from vapor sources by an adequate vertical separation distance. Further assessment may be unnecessary for those buildings outside the lateral inclusion zone unless:

- Preferential transport pathways are present that connect PHC vapor sources to receptors
- Impermeable surface cover (e.g., concrete, asphalt, ice, very large buildings) is so extensive that there is concern whether there is sufficient oxygen in the subsurface to support biodegradation
- Soil conditions are inhospitable to microorganisms (e.g., dry soils with less than 2 percent soil moisture by dry weight) such that biodegradation is insufficient to mitigate the threat of PVI

5. Vertical Separation Distance

Description

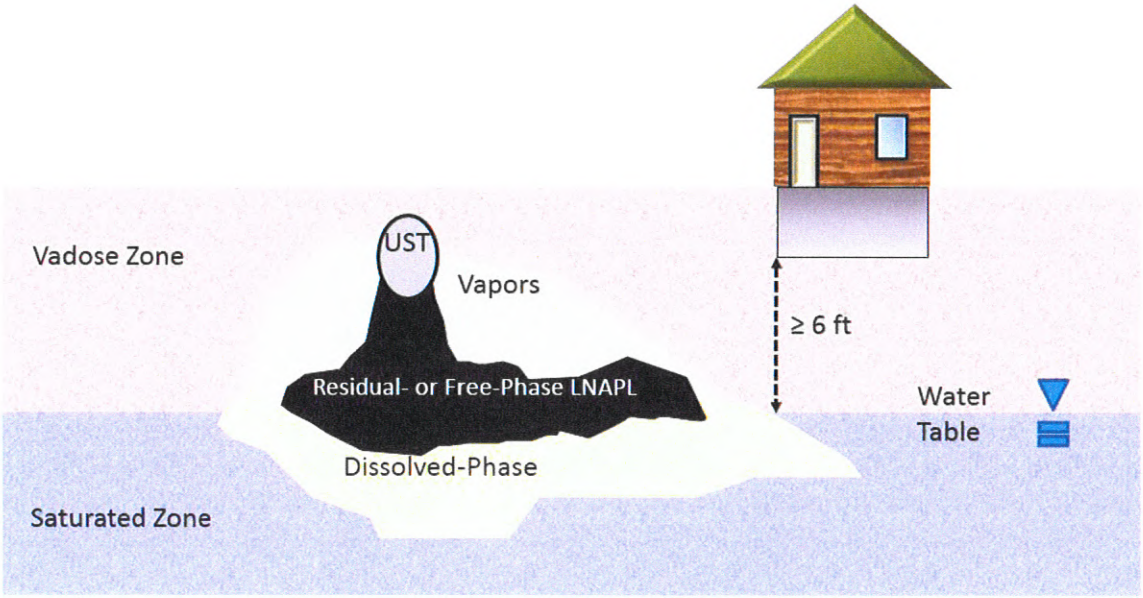
The vertical separation distance is the thickness of clean, biologically active soil (see **Section 9**, p.75) between the highest vertical extent of a contaminant source and the lowest point of an overlying building. This lowest point could be a building basement floor, foundation, or crawlspace surface.

Importance

If the thickness of clean, biologically active soil is sufficient and oxygen and soil moisture are present, aerobic biodegradation will usually degrade vapor-phase PHCs before they can intrude into buildings. EPA (2013a) presents a compilation and analysis of soil gas data from a large number of sites that represent many different hydrogeologic settings where gasoline was released from USTs.[26] This analysis builds on the work of Davis (2009, 2010, 2011a, and 2011b). In addition, EPA (2013a) summarizes the results of a number of parallel efforts (Lahvis, et al., 2013; Peargin and Kolhatkar, 2011; Wright, 2011, 2012). Although these studies used somewhat different data sets, there is a high degree of consistency among them. This consistency supports the establishment of vertical screening distances based on whether PHC contamination is present as LNAPL or dissolved PHCs; that is, the thickness required to aerobically biodegrade PHCs is directly related to the strength of the source. Because LNAPL sources are capable of producing higher concentrations of vapors compared to dissolved sources, the necessary separation distance between receptors and LNAPL is greater than the necessary separation distance between dissolved sources and receptors. At sites where non-PHC fuel additives are present (see **Section 10**, p.81), the vertical separation distance may not be sufficient to protect against vapor intrusion. In this case, additional investigation should be conducted to assess the potential for vapor intrusion.

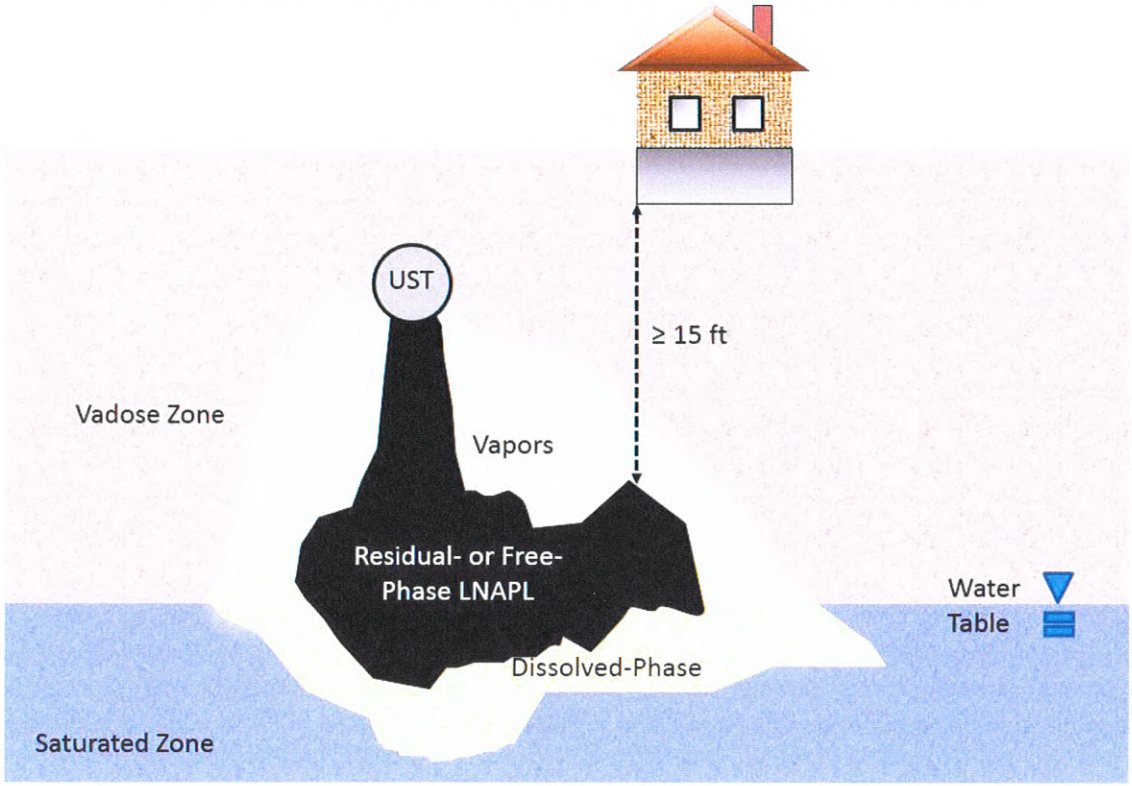
Assessment

The vertical separation distance is measured from the lowest point of the overlying building basement floor, foundation, slab, or crawlspace surface and the highest vertical extent of contamination. For dissolved sources this is the historic high water table elevation; for LNAPL sources this is the top of the smear zone or residual LNAPL in the source area. Vertical separation distances for dissolved plumes and LNAPL sources are schematically depicted in **Figure 6a and 6b**, respectively. Both mobile LNAPL and dissolved contaminant plumes are dynamic and may move from one monitoring event to the next. As discussed in **Section 7** (p.61), periodic monitoring of groundwater flow directions and plume migration are recommended, possibly over more than one annual cycle.



The presence of LNAPL may be determined from direct or indirect evidence. Direct evidence includes measureable accumulations of free product in monitoring wells, an oily sheen or floating globules on the water table, and petroleum hydrocarbon-saturated bulk soil samples.

---



[26] The final report (EPA, 2013a) addresses the peer review comments received. The report, database, and peer review record are accessible on EPA's PVI Compendium Web page: http://www.epa.gov/oust/cat/pvi/index.htm.

REC 4697

TR 1382

(a) Vertical separation distance for dissolved-phase source of PHCs.

(b) Vertical separation distance for LNAPL (residual or mobile phase) source of PHCs.

Figure 6. Vertical Separation Distances Between Source Of PHC Contaminants And Hypothetical Receptor: (a) Dissolved Source, (b) LNAPL Source.

Lahvis et al. (2013) caution that the presence or absence of free-phase LNAPL in monitoring wells may not be a reliable indicator of the presence of residual-phase LNAPL. The absence of LNAPL can only be determined through analysis of core samples. This is important to recognize because free-phase and residual LNAPL have a greater vapor-generating capability than dissolved sources. Indirect evidence includes high concentrations of benzene and other PHCs, often measured as TPH.[27] There is considerable variation and uncertainty in LNAPL thresholds determined from indirect evidence and Lahvis et al. (2013) suggest that multiple indicators of the presence of LNAPL be evaluated. EPA (2013a) selected a benzene concentration of 5 mg/L to differentiate between dissolved and LNAPL sources. A study by Peargin and Kolhatkar (2011) suggests that a dissolved source with benzene greater than 1 mg/L may behave like a LNAPL source in terms of vapor-generating capability. For more information on indicators of LNAPL, see **Section 6** (p.57).

Special Considerations

Preferential transport pathways such as utility conduits typically enter buildings through holes in the foundation or slab and can facilitate the entry of PHC vapors into the building. Consideration should be given to field instrument screening at utility access point(s) as an initial step to determine if the utility is acting as a conduit for vapors. If the transport of vapors from the source area to the building could occur along utility conduits, then vapor sampling inside the utility conduits, manholes, or sumps should be considered in addition to vadose zone and sub-slab soil gas sampling. Any utility sampling program should include safety precautions to protect personnel (e.g., oxygen and combustible gas monitoring, confined-space entry requirements) and to avoid damage to utilities. Specific guidance for utility sampling is available in *A Practical Strategy for Assessing the Subsurface Vapor-to-Indoor Air Migration Pathway at Petroleum Hydrocarbon Sites* (API, 2005).

Vertical separation distances that are usually protective against PVI may not be sufficiently protective in situations where methane is produced in large quantity, such as sites where high-ethanol blends of gasoline (i.e., E-20 or greater) have been released (Ma et al., 2014), or beneath very large buildings, or where the ground surface is covered by extensive impermeable material (e.g., pavement) (EPA, 2013c).

In addition, consideration should be given to whether future new buildings will be constructed within the lateral inclusion zone and whether they may be impacted by PVI.

[27] Toxicological data for TPH fractions may be found in EPA (2009, 2013b), ATSDR (1999), Tveit et al. (1999), and HI DOH (2012). More recently, Brewer et al. (2013) have developed a quantitative method for risk-based evaluation of TPH in PVI investigations.

Recommendation

EPA recommends using the criteria presented in **Table 3** to determine the necessary vertical separation distance between PHC contamination from leaking USTs and an overlying building foundation, basement, or slab. These distances are 6 feet for dissolved vapor sources (beneath buildings of any size) and 15 feet for LNAPL sources (beneath buildings up to 66 feet on the shortest side).[28] Where the respective vertical separation distance is met or exceeded, generally no further investigation for PVI is necessary if there are no precluding factors present (e.g., preferential transport pathways) and the PCH source is not a high-ethanol blend (i.e., E-20 or greater) of gasoline. If the applicable separation distance is not met and where contamination is not in direct contact with an overlying building, then choose one of two options: (1) collect near-slab (exterior) shallow soil gas samples paired with deep (source) soil gas samples, or (2) collect indoor air samples paired with sub-slab soil gas samples. If the potential for PVI cannot be ruled out based on near-slab and deep soil gas sampling, then EPA recommends indoor air sampling paired with sub-slab vapor sampling. If the attenuation factor calculated from results of analysis of the chosen pair or vapor samples indicates that there may be a potential for PVI above applicable exposure limits, EPA recommends gathering additional information and data to determine whether mitigation is appropriate.

Although biodegradation is known to occur for many individual non-PHC fuel additives and classes of additives, the rate of biodegradation in soil gas has not necessarily been rigorously quantified; this is especially true for the lead scavengers EDB and 1,2-DCA. Therefore, for these two chemicals in particular, vertical separation distances recommended in this guide may not be sufficient for petroleum fuel releases that contain EDB and 1,2-DCA and additional investigation may be necessary to assess their potential for vapor intrusion (See **Section 10**, p.81 for more information).

[28] See *3-D Modeling of Aerobic Biodegradation of Petroleum Vapors: Effect of Building Area Size on Oxygen Concentration Below the Slab* (EPA 510-R-13-002)(EPA, 2013c).

REC 4700

TR 1385

Table 3. Recommended Vertical Separation Distance Between Contamination And Building Basement Floor, Foundation, Or Crawlspace Surface.

Media	Benzene	TPH	Vertical Separation Distance (feet)*
Soil (mg/Kg)	≤10	≤ 100 (unweathered gasoline), or ≤ 250 (weathered gasoline, diesel)	6
	>10 (LNAPL)	> 100 (unweathered gasoline) >250 (weathered gasoline, diesel)	15
Groundwater (mg/L)	≤5	≤30	6
	>5 (LNAPL)	>30 (LNAPL)	15

The thresholds for LNAPL indicated in this table are indirect evidence of the presence of LNAPL. These thresholds may vary depending on site-specific conditions (e.g., soil type, LNAPL source). The value of 5 mg/L benzene is from EPA (2013a, p.31). A study by Peargin and Kolhatkar (2011) suggests that a dissolved source with benzene greater than 1 mg/L may behave like a LNAPL source in terms of vapor-generating capability. Decision-makers may have different experiences with LNAPL indicators and may use them as appropriate. For more information, see **Section 6** (p.57) and **Figure 7** in particular.

Bulk soil samples should be analyzed for Total Petroleum Hydrocarbon (TPH) and BTEX (plus any other potential contaminants). The objective of measuring TPH is to quantify the total vapor phase concentration of PHCs. TPH may be analyzed by methods appropriate for the type of fuel released. These methods may be designated as TPH-gasoline (or sometimes gasoline range organics or GRO), TPH-diesel (or sometimes diesel range organics or DRO). Method TO-15 (see http://www.epa.gov/ttn/amtic/files/ambient/airtox/to-15r.pdf) by itself only measures a small fraction of PHCs that may be present in the vapor-phase. TO-15 analyses require a correction factor to estimate bulk TPH. An extended TO-15 analysis can provide such an estimate. For more information on TPH in vapor intrusion studies, see Brewer et al. (2013).

*The vertical separation distance represents the thickness of clean, biologically active soil between the source of PHC vapors (LNAPL, residual LNAPL, or dissolved PHCs) and the lowest (deepest) point of a receptor (building basement floor, foundation, or crawlspace surface).

6. Mobile And Residual Light Non-Aqueous Phase Liquid (LNAPL)

Description

LNAPLs released from petroleum USTs are typically fuel products such as gasoline and diesel fuel. Fuel products are comprised of a large number of volatile and semi-volatile PHCs and synthetic additives. Among these compounds are some that are volatile and some that are semi-volatile. Newer, unweathered releases typically contain a higher proportion of more volatile PHCs than do older releases that may be more weathered and depleted in the more volatile PHCs. Similarly, gasoline contains a higher proportion of more volatile PHCs than does diesel fuel and other middle distillates such as heating oil and kerosene. Vapors emanating from dissolved-phase sources are primarily BTEX and other aromatic hydrocarbons, and relatively water-soluble PHCs. Vapors emanating from LNAPL sources contain the same constituents in addition to a sizeable fraction of aliphatic and relatively insoluble hydrocarbons (e.g., naphthalene), especially if the source is large or unweathered (Lahvis, et al., 2013; EPA, 2013).

Importance

Depending upon the volume of the release and the characteristics of the soil, PHC vapors from LNAPL sources can reach concentrations high enough to deplete oxygen needed by microorganisms to biodegrade them. Compared to a dissolved plume, a LNAPL plume from a leaking UST does not typically migrate far from the site of release (e.g., the leaking UST or connected piping). However, the larger the mass of the release the greater the potential for the LNAPL plume to migrate. When LNAPL underlies a receptor or comes into direct contact with a basement, foundation, or slab, there is increased potential for explosive levels of vapors to accumulate within the building or other structure.

Residual PHCs are non-mobile in the subsurface and occur when the release stops prior to the accumulation of a sufficient amount of LNAPL for flow to occur, or when a fluctuating water table smears the LNAPL across the water table and reduces the LNAPL saturation of the soil. This smearing inhibits the lateral migration of LNAPL. Although residual contamination is not free flowing, residual sources represent a large mass of contaminants that can persist for long periods of time and generate considerable volumes of PHC vapors as well as dissolved-phase contaminants.

Monitoring wells with residual LNAPL may not have a measurable accumulation of LNAPL so they look exactly like monitoring wells with only dissolved contamination (that is, there is no measurable LNAPL in the monitoring well). However, due to the presence of residual LNAPL, the vapor source area acts like a free-phase LNAPL source in terms of vapor-generating character (Lahvis, et al., 2013). A study by Peargin and Kolhatkar (2011) suggests that a dissolved source with benzene concentration greater than 1 mg/L may have the same vapor-generating capacity as a LNAPL source. This situation is depicted in **Figure 7**.

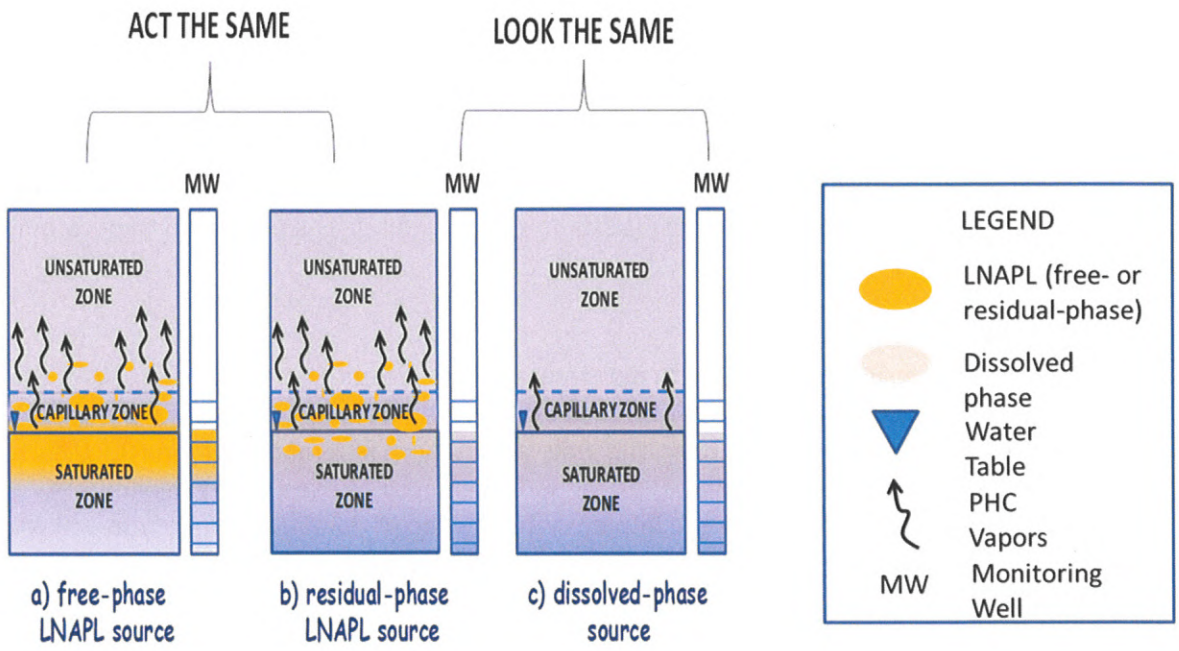

Figure 7. Conceptual Model Illustrating The Potential For Vapor Intrusion For a) Free-Phase LNAPL Source, b) Residual-Phase LNAPL Source, And c) Dissolved-Phase Source (Source: Lahvis, et al., 2013. Reprinted from *Groundwater Monitoring & Remediation* with permission of the National Ground Water Association. Copyright 2013.)

Assessment

The distinction between petroleum contamination present as LNAPL and contamination present purely as a dissolved phase is important. Unfortunately, there is no precise concentration threshold between dissolved phase PHCs and PHCs present in a mixed phase that includes LNAPL.[29] EPA (2013) used a threshold for the benzene groundwater concentration equal to 5 mg/L and a total petroleum hydrocarbon (TPH) threshold groundwater concentration of 30 mg/L for identification of LNAPL sites. The TPH threshold adopted by EPA (2013) is based on the calculated approximate average ratio of the concentration of benzene to TPH in groundwater at UST sites. A site with a LNAPL source was identified on the basis of either the benzene or TPH groundwater concentration exceeding the threshold. The thresholds adopted for identifying LNAPL sites based on soil concentrations are 10 mg/Kg benzene, 100 mg/Kg TPH for unweathered gasoline, and 250 mg/Kg TPH for diesel or weathered gasoline.

[29] Table 4 in EPA (2013) presents a variety of direct and indirect indicators of LNAPL. For example, Bruce, et al. (1991) suggest groundwater concentrations greater than one-fifth (0.2) of the effective solubility of LNAPL as indirect evidence of the presence of LNAPL. However, because the effective solubility depends on characteristics of the LNAPL mass (e.g., composition, weathering); there is uncertainty in the threshold. Additional discussions of screening concentrations for LNAPL are presented in *Evaluating Hydrocarbon Removal from Source Zones and its Effect on Dissolved Plume Longevity and Concentration* (API, 2002), and ITRC (2014).

Special Considerations

Direct means for detecting the presence of LNAPL include measurable accumulations of free product in monitoring wells, an oily sheen on the water, and saturation of bulk soil samples.[30] The presence of residual LNAPL may not be recognizable from monitoring well data. This is because the soil is not sufficiently saturated with LNAPL to allow it to flow into wells. Lahvis et al. (2013) suggest that multiple indicators (both direct and indirect) be evaluated to determine whether or not LNAPL is present.

Recommendation

EPA recommends subsurface sampling to determine the full extent and location of LNAPL (both mobile LNAPL and residual). LNAPL may be present even when there is no measureable accumulation of free product in a monitoring well. In addition, federal regulations (40 CFR 280.64) require that when free product is present, it must be "removed to the maximum extent practicable as determined by the implementing agency." Effective source removal will mitigate a long term source of PHC vapors as well as mitigate dissolved and residual LNAPL contamination.

EPA recommends analyzing bulk soil samples collected in the source area for TPH (e.g., gasoline or diesel depending on which fuels were stored on site) and specific petroleum constituents (e.g., BTEX and other volatile and semi-volatile organic chemicals, and fuel additives). EPA also recommends analysis of LNAPL samples (if present) to determine the degree of weathering and potential for vapor generation.

7. Groundwater Flow And Dissolved Contaminant Plumes

Description

Contaminant plumes are dynamic, three-dimensional distributions of contaminants in groundwater. Contaminants dissolved in groundwater can migrate with flowing groundwater thereby spreading contamination. In some aquifers, where the direction and speed of groundwater flow are stable, the plumes are usually long and narrow. Other plumes appear to spread in both the transverse as well as the longitudinal direction. This apparent transverse dispersion may be the direct result of changes in the direction of groundwater flow. What may appear to be transverse dispersion is actually longitudinal dispersion occurring in different directions as the direction of flow changes (EPA, 2005; Wilson, 2003).

Importance

The potential for PVI from dissolved PHC contaminant plumes is typically limited to sites where there are high concentrations of dissolved contaminants or the plume is in direct contact with a building foundation, basement, or slab. A study by Peargin and Kolhatkar (2011) suggests that a dissolved source with benzene greater than 1 mg/L may have the same vapor-generating capacity as a LNAPL source.

Assessment

Contaminant plumes generally necessitate three-dimensional monitoring to assess the transient behavior of groundwater flow and the movement of contaminant plumes (EPA, 2004a, b). Contaminant plumes migrate with flowing groundwater, which can exhibit seasonal variations as well as responses to pumping, tides, or stage of a nearby river.[31] Groundwater flow directions can and often change over time, and may necessitate periodic monitoring over more than one annual cycle to understand the groundwater flow regime at a given site.

(Note: This monitoring need not delay additional investigation activities and measures to mitigate or remediate threats to safety and health.) As the plume migrates, appropriate adjustments to the sampling plan should be made to ensure that potential receptors are

---

[31] Groundwater flow directions can change frequently and relatively quickly. Changes in groundwater flow directions may be more prevalent than is realized, because the variation in the direction of groundwater flow is rarely evaluated in any formal way (EPA, 2005). Wilson (2003) studied data from a site in North Carolina where groundwater flow was influenced by the stage of a nearby river. Over the course of one year of monthly monitoring, groundwater flow directions fluctuated by 120 degrees. Wilson et al. (2005) also studied data from a gas station site in New Jersey. Over a six-year period groundwater monitoring data were collected on 23 occasions; the predominant flow direction was 90-degrees from the presumed direction on which the conceptual model was constructed, and the direction of flow fluctuated by nearly 180 degrees. Mace et al. (1997) studied the variation in groundwater flow directions at 132 gas stations in Texas. Fluctuations in flow directions occurred over a range of 120 degrees. Goode and Konikow (1990) characterized a site where PHCs leaked to the water table. Groundwater flow directions changed nearly 90 degrees in less than four months in response to changing flow conditions in a nearby intermittent stream.

protected. If new PHC releases to groundwater occur, then appropriate mitigation steps can be implemented.

Plume monitoring networks should be able to detect changes in plume boundaries as well as fluctuations in the concentrations of geochemical parameters and contaminant concentrations. Collection of samples from the contaminant plume is needed to determine the extent of contamination and provide information that can be used to estimate the vapor generation capacity of the dissolved contamination. The contaminant plume should be surrounded by sampling points that are free of contamination (i.e., *clean monitoring points*).

Conventional monitoring wells may provide an incomplete picture of the true distribution of contaminants in groundwater. If the length of the screen in a monitoring well is long compared to the thickness of the plume of contamination, the sample obtained will be diluted by the inflow of clean(er) groundwater from above or below the plume. Also, plumes may dive below the screened interval of the wells leading to the false impression that the plume is shorter than it actually is (EPA, 2005).

Special Considerations

Dissolved plumes are dynamic and contamination may migrate beneath buildings over time. This is best evaluated by determining the range of fluctuation in groundwater flow direction and water table elevations beneath buildings over at least one annual cycle. However, in the interim, the remaining PVI-related activities should continue. Preferential transport pathways, if present, may facilitate the intrusion of petroleum vapors into buildings.[32] When contaminant plumes intersect preferential transport pathways, the spread of contamination can be very rapid compared to the velocity of groundwater flow through the soil.

Volatilization of contaminants from the plume into soil gas is greatly reduced when a plume dives beneath the water table surface. Volatile contaminants diffuse more slowly through the water column than through soil gas.

Recommendation

EPA recommends groundwater monitoring and sampling to determine the depth to contaminated groundwater and the vertical distribution of contaminants in the water column beneath overlying buildings[33]. Due to the transient nature of groundwater migration, EPA recommends periodic monitoring and sampling over more than one annual cycle to fully

---

[32] Dissolved petroleum contaminants may threaten building inhabitant's health through their water supply rather than through vapor intrusion. Exposure may occur from wells drawing from a contaminated plume, or contamination permeating the water supply piping. Though fuel constituents generally impart a disagreeable odor and taste, building occupants may still be exposed to potentially harmful levels of contaminants. Such exposure may occur when PHCs volatilize from the dissolved phase during showering or washing clothes and dishes, or through ingesting contaminated water. Identifying the mechanism of exposure is important because methods for remediation/mitigation of PVI will be different than treatment or remediation of contaminated groundwater.

[33] If groundwater samples contain greater than 30 mg/L TPH (or greater than 5 mg/L benzene), it is possible that residual LNAPL is present (see **Section 6**, p.57).

understand the groundwater flow regime at a given site. Where the respective vertical separation distance (see **Section 5**) is met or exceeded, generally no further investigation for PVI is necessary if there are no precluding factors present (e.g., preferential transport pathways) and the PCH source is not a high-ethanol blend (i.e., E-20 or greater) of gasoline. If the applicable separation distance is not met and where contamination is not in direct contact with an overlying building, then choose one of two options: (1) collect near-slab (exterior) shallow soil gas samples paired with deep (source) soil gas samples, or (2) collect indoor air samples paired with sub-slab soil gas samples. If the potential for PVI cannot be ruled out based on near-slab and deep soil gas sampling, then EPA recommends indoor air sampling paired with sub-slab vapor sampling. If the attenuation factor calculated from results of analysis of the chosen pair or vapor samples indicates that there may be a potential for PVI above applicable exposure limits, EPA recommends gathering additional information and data to determine whether mitigation is appropriate.

Even in cases where there is no threat of PVI from contaminated groundwater, EPA recommends that the plume be assessed to determine if remediation is necessary to prevent ingestion of contaminated drinking water and protect and restore actual or potential sources of drinking water.

8. Soil Gas Profile

Description

Aerobic biodegradation of PHC vapors occurs in many subsurface environments (Lahvis, Baker, and Behr, 1998; McHugh, et al., 2010; Roggemans, 1998; Roggemans, Bruce, and Johnson, 2002; ZoBell, 1946; Atlas, 1981; Leahy and Colwell, 1990; DeVaull, 2007). The soil gas profile can provide confirmation that aerobic biodegradation is occurring in the subsurface. Decreasing oxygen concentration and increasing carbon dioxide and methane concentrations indicate biodegradation of PHCs (Hult and Grabbe, 1988). Shallow soil gas typically contains water vapor and fixed gases: nitrogen, oxygen, carbon dioxide, carbon monoxide, and argon. These gases infiltrate into the soil from the atmosphere. Vapor phase PHC contamination may be the result of volatilization from mobile LNAPL released into the subsurface, residual soil contamination (including the smear zone), and dissolved phase contamination. The lower proportion of volatile hydrocarbon compounds in diesel fuel will lead to a comparatively smaller vapor plume in comparison to the release of a similar volume of gasoline (Prince and Douglas, 2010; Marchal, et al., 2003). In addition to PHCs, soil gas may also contain degradation products from the breakdown of PHCs and naturally occurring organic matter. The principal gases resulting from the biodegradation of PHCs are carbon dioxide (under aerobic conditions) or methane (under anaerobic conditions).

Figure 8 presents a characteristic vertical concentration profile in the unsaturated zone; oxygen concentrations decrease with depth and PHCs (including methane) and carbon dioxide

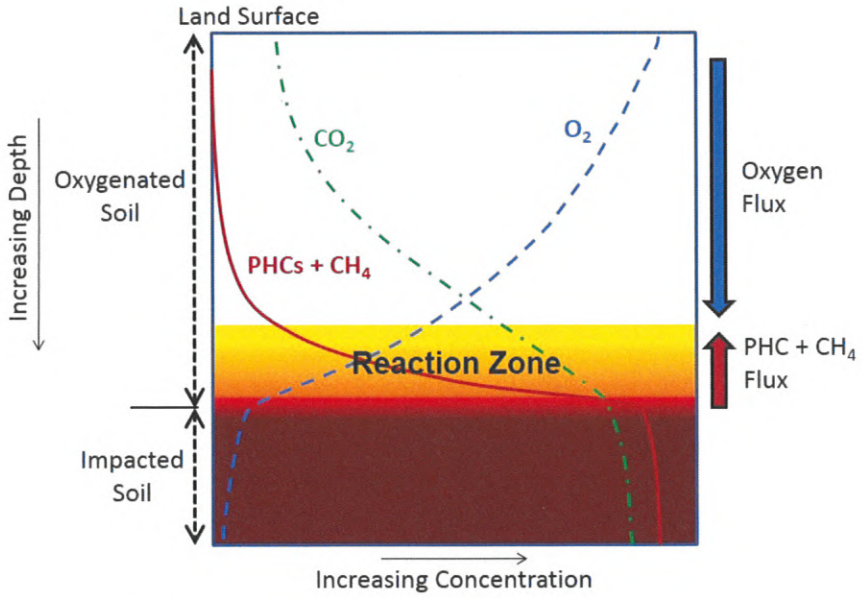

Figure 8. Typical Vertical Concentration Profile In The Unsaturated Zone For PHCs (Plus Methane), Carbon Dioxide And Oxygen

concentrations increase with depth toward the source of contamination. This typical vertical profile may vary somewhat in shape depending on site-specific conditions (Roggemans, Bruce, and Johnson, 2002). During aerobic biodegradation in unsaturated soils, PHCs degrade, oxygen is consumed, and carbon dioxide is produced. The aerobic biodegradation zone is within oxygenated soil (generally greater than 1 percent oxygen in soil gas). In the oxygenated soil zone (where aerobic biodegradation occurs between land surface and the depth of impacted soil) the decrease in PHC concentrations is typically quite rapid and occurs over a narrow interval (the reaction zone in **Figure 8**) (Abreu, Ettinger, and McAlary, 2009).

The impacted soil zone, which is anaerobic, is characterized by the maximum PHC concentrations (and often LNAPL) and biodegradation is slow (EPA, 2012a). Generally, PHC vapor concentrations will be much greater adjacent to a LNAPL source than adjacent to a dissolved hydrocarbon plume. If PHC concentrations are high enough, available oxygen may be depleted, which in turn limits aerobic biodegradation. The core of any PHC contaminant mass is typically depleted with respect to oxygen, thus anaerobic biodegradation of LNAPL or other organic sources (e.g., ethanol) can produce significant amounts of methane (Anderson and Lovley, 1997; Wiedemeier, et al., 1999; Koenigsberg and Norris, 1999; Ma et al., 2014). Methane readily biodegrades under aerobic conditions and, when present, will create an additional oxygen demand (Jewell and Wilson, 2011; Ma, et al, 2012). High concentrations of methane, oxygen, and a source of ignition can create a fire or explosion hazard in confined spaces (e.g., utility vaults and passages, basements, or garages) (Ma et al., 2014). For additional information on evaluating the presence of methane and potential hazards, see ASTM's "*New Practice for Evaluating Potential Hazard Due to Methane in the Vadose Zone*".[34]

Differences between near-slab soil gas profiles and sub-slab soil gas profiles are reported in two EPA modeling studies: the conceptual model scenarios report EPA (2012b) and the building size modeling report for PVI (EPA, 2013a). However, EPA (2012b) assumed that building foundations, basements, and slabs were impermeable and, thus, oxygen transport was not simulated through the foundation, basement, or slab into the subsurface beneath the building. Simulations presented in EPA (2013a) allowed for oxygen transport using reasonably expected oxygen permeability values for concrete (Fischer et al., 1996; McHugh, DeBlanc, and Pokluda, 2006; Lundegard, Johnson, and Dahlen, 2008; Patterson and Davis, 2009; Tittarelli, 2009). When oxygen transport is accounted for, the differences in soil gas profiles were less pronounced between near-slab and sub-slab samples very close to the building basement and slab. Thus, near-slab soil gas samples can be substituted for sub-slab samples in situations where dissolved contamination is present within 6 feet of (but not in contact with) a building basement floor, foundation, or crawlspace surface, and where LNAPL is present within 15 feet of (but not in contact with) a building basement floor, foundation, or crawlspace surface. For dissolved sources this holds for buildings of any size, and for LNAPL sources it applies to buildings with the shortest side being no longer than 66 feet (EPA, 2013a). Deep soil gas samples are needed to determine the depth to contaminated soil and the thickness of clean,

[34] The new ASTM methane guide is accessible at http://www.astm.org/DATABASE.CART/WORKITEMS/WK32621.htm

biologically active soil necessary to attenuate PHC vapors. Shallow soil gas samples should be paired with deep (near source) soil gas samples to evaluate the strength of the PHC vapor source and the attenuation of PHC vapors.

Importance

The potential for PVI is a function of the oxygen demand exerted by all biodegradable vapors, not just the key chemicals of potential concern (Jewell and Wilson, 2011; Ma, et al., 2012). When present, volatile PHCs and methane also exert an oxygen demand that may limit aerobic biodegradation of benzene (Abreu, Ettinger, and McAlary, 2009; Wilson, 2011). An estimate of the biodegradation rate can be determined from the stoichiometric relationship between the flux of oxygen, carbon dioxide, and methane (Lahvis and Baehr, 1996). PHC vapor concentrations generally decrease with increasing distance from a subsurface vapor source. At a relatively short distance from the source, concentrations of PHCs in soil gas will typically fall below potentially significant levels of concern provided that oxygen replenishment is adequate to ensure complete aerobic biodegradation. Lahvis, Baehr, and Baker (1999) observed that PHC vapors from a dissolved plume were almost completely degraded within 1 meter (3.3 feet) above the water table and that significant transport of PHC vapors may only be significant if the vapor source is LNAPL. This is consistent with the findings of EPA's (2013b) PVI database analysis report and Lahvis et al. (2013).

Assessment

Soil gas samples provide information on the distribution of contamination near the source area, whether biodegradation is occurring, and how effective it is in reducing the potential for PVI. When there is an impermeable surface cover adjacent to a building, soil gas probes should be installed beneath the surface in order for the soil gas profile to adequately characterize conditions below the surface. For very large buildings, or where there is extensive impermeable surface cover and the vapor source is relatively shallow, additional investigation is recommended to verify that biodegradation is occurring beneath the building.[35] Vapor samples should be analyzed for PHCs (and non-PHC fuel additives), methane, oxygen, and carbon dioxide (Lahvis, Baehr, and Baker, 1999).

---

[35] EPA (2013a) presents modeling results for a variety of soil types, building sizes, vapor source strengths, and vertical separation distances. These results, while not exhaustive, indicate that for dissolved sources and very large buildings, an oxygen shadow does not form, thus the subsurface stays sufficiently oxygenated to support aerobic biodegradation and preclude the potential for PVI. For LNAPL sources, an oxygen shadow was not observed to form beneath buildings up to 66 feet on the shortest side. This length represents the threshold below which oxygen replenishment is sufficient to support aerobic biodegradation; above this length oxygen replenishment may be impeded and there may be insufficient oxygen present to support aerobic biodegradation. For larger buildings underlain by LNAPL within 15 feet of the foundation, basement, or slab, sub-slab soil gas sampling paired with indoor air sampling is necessary to assess whether PVI is occurring. Another potential concern for large buildings and extensive, impermeable surface cover (e.g., asphalt, concrete) is formation of a moisture shadow, which represents soil moisture content too low to support microbial biodegradation (see **Section 9,** p.75, for more information).

An estimate of the total oxygen demand can be determined in two ways: sample for methane and petroleum hydrocarbons (PHCs); or sample and measure the oxygen demand for all the organic compounds in the soil gas at the source.[36] If methane and all the PHCs in soil gas are measured, these concentrations should be converted to an equivalent concentration of benzene and summed. The total oxygen demand of the aggregate of methane and the PHCs (expressed as an equivalent concentration of benzene) can be used to determine an attenuation factor (α) that can be used along with the actual concentration of benzene in soil gas at the source to determine whether aerobic biodegradation is capable of degrading the PHC vapors to acceptable concentrations (see **Section 12,** p.106, **Figure 9**, p.101, and **Figure 10,** p.103).

In some cases, relatively shallow soil gas samples (less than five feet below ground surface) will be needed to characterize active biodegradation zones in the shallow soil (e.g., in the presence of shallow contamination sources). Some state regulatory programs do not allow soil gas sampling at depths less than 5 feet based on the concern that accurate sampling may not be possible at shallow depths because air from the surface may leak into the sample. However, recent research has shown that the collection of accurate shallow-soil gas samples is possible at depths as shallow as 2 feet below ground surface using appropriate field methods (e.g., leak testing), such as those documented in *Temporal Variation of VOCs in Soils from Groundwater to the Surface* (EPA, 2010). It is also possible under certain conditions to collect representative soil gas samples using previously installed groundwater monitoring wells (see Wilson et al., 2014).

Special Considerations

There are several factors that can limit replenishment of oxygen to deep soils. These include presence of low permeability layers, concrete or asphalt covering at the surface, high soil moisture from a recent rainfall event or from irrigation, and buildings that are so large that oxygen is depleted beneath the center of the building (Patterson and Davis, 2009). However, a recent study by EPA (2013a) indicates that for an oxygen shadow[37] to form beneath a building, the PHC vapor source must be shallow LNAPL and the building must be greater than 66 feet in length on the shortest side. For simulations with dissolved sources, no oxygen shadow formed even under a square building with sides that were 2,073 feet in length.

At sites with a new release or unweathered LNAPL source, the oxygen demand will be high. It is important to determine whether temporal variations in oxygen flux into the vadose zone will limit the effectiveness of aerobic biodegradation, potentially resulting in intermittent vapor intrusion impacts. For such sites, more than one round of soil gas monitoring may be needed to confirm that aerobic biodegradation consistently prevents PVI impacts at the site.

[36] EPA recommends using modified Method TO-15 (*see* http://www.epa.gov/ttn/amtic/files/ambient/airtox/to-15r.pdf) for organic compounds. The concentration of methane measured as a fixed gas can then be added to the results of TO-15 to give an approximation of TPH.

[37] For the purposes of this modeling study, an oxygen shadow is defined as less than 1 percent oxygen.

Recommendation

EPA recommends that soil gas samples be analyzed for PHCs, non-PHC fuel additives, methane, oxygen, and carbon dioxide. Sampling for nitrogen (and other fixed gases) in soil gas can provide a check on the quality of the analyses since the sum of these gases should be 100 percent. If they are substantially less than 100 percent, then some constituents are unaccounted for and the analyses should be interpreted with caution.

For buildings of any size within the lateral inclusion zone if the vertical separation distance between the building basement, foundation, or slab and dissolved contamination is less than 6 feet, but not in contact with the building EPA recommends that near-slab soil gas samples paired with deep (near source) soil gas be collected. For buildings up to 66 feet on the shortest side that directly overlie LNAPL masses, and the vertical separation distance is less than 15 feet (but the building is not in direct contact with LNAPL), EPA recommends collection of near-slab soil gas samples paired with deep (near source) soil gas samples. Near-slab soil gas samples should be collected from each side of the building and as close to the building as practicable. If the attenuation factor calculated from results of analysis of the chosen pair or vapor samples indicates that there may be a potential for PVI above applicable exposure limits, EPA recommends gathering additional information and data to determine whether mitigation is appropriate. If contamination is in direct contact with an overlying building (and thus, collection of shallow soil gas samples is not possible), indoor air sampling is recommended.

In addition, for very large buildings or where there is extensive impermeable surface covering, EPA recommends that near-slab or sub-slab soil gas samples be collected if there is concern that these conditions may impede the flux of oxygen to the subsurface and create an oxygen or soil moisture shadow.

9. Clean, Biologically Active Soil

Description

For a PVI investigation, clean soil does not necessarily mean that it is contaminant-free, but rather that the level of any contamination present is low enough so that the biological activity of the soil is not diminished and the subsurface environment will support sufficient populations of microorganisms to aerobically biodegrade PHC vapors. This means that LNAPL is not present. The oxygen demand of all of the contamination present in the soil should not deplete the available supply of oxygen to such an extent that the rate of biodegradation is reduced.

Effective aerobic biodegradation of PHCs depends on the soil having sufficient oxygen and enough moisture to provide a habitat for adequate populations of active microorganisms. Although most soils contain indigenous microorganisms capable of degrading PHC vapors, typically there is an acclimation period between the time they are exposed to the PHC vapors and the time they begin to biodegrade the vapors. Prior exposure to PHCs has been observed to both increase the number of microbes and the microbial mass available for biodegradation of the PHCs and consequently speed up the degradation rate (ZoBell, 1946; Moyer, et al., 1996; Phelps and Young, 1999; and Siddique, et al., 2007).

The habitat of soil bacteria is the thin film of water held to the surface of soil particles by capillary attraction. EPA (2013a) notes that soil moisture content greater than 2 percent is adequate to support biodegradation activity (Leeson and Hinchee, 1996), although biodegradation is limited when the moisture content is at or below the permanent wilting point (Zwick, et al., 1995; Holden, Halverson, and Firestone, 1997). Adequate soil moisture is also indicated if the landscape supports the growth of non-irrigated vegetation (Riser-Roberts, 1992).

Certain geologic materials do not qualify as biologically active soil and should not be included in the vertical separation distance (see **Section 5**, p.48). These geologic materials include:

- Coarse sand and gravel with a low content of silt, clay, and organic matter, and low moisture content that is less than 2 percent dry weight
- Fractured, faulted, or jointed consolidated rock
- Consolidated rock with solution channels (i.e., karst)

Importance

Effective aerobic biodegradation of PHCs depends on a thick layer of soil having sufficient oxygen and enough soil water to provide a habitat for adequate populations of active microorganisms. If oxygen is present, these organisms will generally consume available PHCs. Furthermore, aerobic biodegradation of petroleum compounds can occur relatively quickly, with degradation half-lives as short as hours or days under some conditions (DeVaull, 2007).

Some petroleum compounds can also biodegrade under anaerobic conditions; however, above the water table, where oxygen is usually available in the soil zone, this process is less important because it is generally much slower than aerobic biodegradation (Widdel, Boetius, and Rabus, 2006; Bailey, Jobson, and Rogers, 1973; and Bruce, Kolhatkar, Cuthbertson, 2010).

Assessment

Scientific research and site characterizations have demonstrated that microorganisms capable of aerobically degrading many PHCs are present in nearly all subsurface soil environments (ZoBell, 1946; Atlas, 1981; Wilson, et al., 1986; Leahy and Colwell, 1990; Bedient, Rifai, and Newell, 1994; EPA, 1999). A number of well-characterized field studies demonstrate extensive aerobic biodegradation of PHC vapors in unsaturated soils (Kampbell, et al., 1987; Ostendorf and Kampbell, 1991; Ririe and Sweeney, 1995; Ririe, et al., 1998; Ostendorf, et al., 2000; Hers, et al., 2000; Roggemans, Bruce, and Johnson, 2002; Sanders and Hers, 2006; Davis, Patterson, and Trefry, 2009; Patterson and Davis, 2009; Lahvis, Baehr, and Baker, 1999; and Lavhis and Baehr, 1996). Several of these studies document vapor concentrations at least two to three orders of magnitude lower than would be predicted to occur merely by simple diffusion in the absence of biodegradation.

EPA (2013a) presents findings of an analysis of a large number of vapor samples from leaking UST sites. These results, which are consistent with several recent analyses of different PVI databases (and which are summarized in the report), indicate that in most settings, PHC vapors are biodegraded over relatively short distances in clean, biologically active soil.

Special Considerations

Preferential transport pathways are avenues of least resistance to the migration of contaminants whether in the dissolved phase, LNAPL phase, or vapor phase. The presence of preferential transport pathways can increase the speed at which contamination moves through the subsurface such that contaminants may not biodegrade by the time they reach receptors. Preferential transport pathways include both natural and man-made features (e.g., solution channels, gravel layers, utility corridors and excavations). Natural geologic materials such as coarse sand and gravel with a low content of silt and clay; fractured consolidated rock; or consolidated rock with solution channels, may not have enough soil moisture in contact with soil gas to support adequate densities of biologically active microorganisms. Particularly in cases with shallow contamination, site investigations should evaluate whether a sufficiently thick layer of clean, biologically active soil is present below buildings in the lateral inclusion zone.

In addition, beneath very large buildings or under areas of extensive impermeable surface cover, soil moisture content may be lower than optimal[38] to support an adequate population of biologically active microorganisms necessary to degrade PHC vapors and prevent PVI (see Tillman and Weaver, 2007; EPA, 2013b).

---

[38] Such reduced soil moisture beneath large buildings is referred to as a *soil moisture shadow*.

Recommendation

Based on EPA (2013a), clean, biologically active soil does not contain LNAPL, EPA recommends LNAPL thresholds of 100 mg/Kg TPH (fresh gasoline) and 250 mg/Kg TPH (weathered gasoline and diesel). Except for the geological materials identified in *Special Considerations*, most soils contain indigenous microorganisms, sufficient oxygen, and adequate soil moisture necessary for degrading PHC vapors. Thus, it is typically not necessary to run microcosm studies or plate counts to test for microbial presence. However, if the conditions at the site are uncertain for supporting aerobic biodegradation, EPA recommends that appropriate samples be collected and analyzed to verify conditions at the site.

Due in part to difficulties in measuring this level of accuracy in the field, EPA recommends vertical separation distances of 6 feet for purely dissolved sources of PHCs and 15 feet for LNAPL sources. These distances are believed to be conservative in most environmental settings. The vertical separation distances described in this guidance (see **Table 3** in **Section 5**, p.52) should not be used at sites where the geologic materials may not have enough soil moisture in direct contact with soil gas. EPA recommends collection and analysis of adequate soil samples for soil moisture, which should be greater than 2 percent by dry weight. In situations where densities of biologically active microorganisms may not be adequate to biodegrade PHCs then soil gas samples should be collected following the recommendations in **Section 8**. If the attenuation factor calculated from results of analysis of the chosen pair or vapor samples indicates that there may be a potential for PVI above applicable exposure limits, EPA recommends gathering additional information and data to determine whether mitigation is appropriate.

10. Non-PHC Fuel Additives

Description

Petroleum fuels are comprised of hundreds of compounds; both natural components of petroleum as well as a number of synthetic (non-PHC) additives intended to improve certain performance properties of the fuel. Contaminants other than PHCs may be present at a site as the result of releases of petroleum fuels that contain additives, including alcohols (e.g., ethanol and tertiary-butyl alcohol [TBA]), ethers (e.g., MTBE), organic lead (e.g., the tetraalkyl lead compounds: tetraethyl lead [TEL], and tetramethyl lead [TML]), and lead scavengers (e.g., ethylene dibromide [EDB] and 1,2-dichloroethane [1,2-DCA]).[39] Non-petroleum contaminants may also be from releases of substances (e.g., chlorinated solvents) other than petroleum fuels. Their presence may be from prior uses of the site or as the result of migration from an off-site source (e.g., dry cleaner, chemical plant, landfill).[40]

Importance

When assessing the potential threat of vapor intrusion, the presence of non-PHC fuel additives may pose a variety of additional challenges. Depending on the class of additive, the challenges include:

- Uncertainty regarding the aerobic biodegradation rates of some additives as well as some that do not biodegrade aerobically (or do not biodegrade quickly enough) in the shallow subsurface
- Biodegradation of an additive such as ethanol that consumes oxygen that would otherwise be available for biodegradation of other PHCs and produces a VOC (methane), which may migrate into buildings and hasten the spread of PHC vapors
- Toxicity levels of some additives are below the detection limit of conventional analytical methods

---

[39] Although leaded gasoline, which also contains the lead scavengers EDB and 1,2-DCA, is no longer used for automotive fuel, it is still used for certain off-road applications such as automobile racing and in aviation fuel (Avgas). At these and older automotive fuel sites where leaded gasoline was released to the subsurface, lead scavengers may be present and could represent a potential source of vapors that should be assessed. For more information about lead scavengers, see Appendix F in *Evaluation Of Empirical Data To Support Soil Vapor Intrusion Screening Criteria For Petroleum Hydrocarbon Compounds* (EPA, 2013).

[40] While these substances are not the primary focus of a petroleum UST release investigation (including site characterization and subsequent cleanup, if necessary), there is the possibility that their presence may be detected through the use of certain analytical methods for identification of contaminants in groundwater, soil, and vapor samples. In particular, both EPA methods 8260B (EPA, 1996a) and 8021B (EPA, 1996b) can detect a number of volatile chlorinated solvents that are not associated with petroleum fuels or typically stored in USTs. The Leaking Underground Storage Tank Trust Fund cannot be used to assess or cleanup contamination from non-UST and non-petroleum sources. Volatile chlorinated solvents (e.g., PCE, TCE, TCA, Carbon tetrachloride, Chloroform) also do not biodegrade under aerobic conditions, therefore their potential for vapor intrusion should instead be assessed using the *OSWER Final Guidance For Assessing and Mitigating the Vapor Intrusion Pathway From Subsurface Sources to Indoor Air* (OSWER Publication 9200.2-154)(EPA, 2015). Should any contaminants from non-UST sources be discovered at a leaking UST site, contact the appropriate state or federal implementing agency.

The separation distances described in this document (**Section 5**, Table 3, p.52) and the protectiveness provided by clean, biologically active soil against vapor intrusion by PHCs may be insufficient to protect against vapor intrusion by non-PHC fuel additives. Additional investigation should be conducted where certain additives are present. The following narrative provides additional information on several additives and introduces the Vapor Intrusion Screening Levels (VISL) Calculator, which may be particularly useful when investigating vapor intrusion from non-PHC fuel additives.

Although biodegradation is known to occur for many individual additives and classes of additives,[41] the rate of biodegradation in soil gas has not necessarily been rigorously quantified; this is especially true for the lead scavengers EDB and 1,2-DCA. Therefore, for these two chemicals in particular, vertical separation distances recommended in this guide may not be sufficient for petroleum fuel releases that contain EDB and 1,2-DCA and additional investigation may be necessary to assess their potential for vapor intrusion. Note: Though the use of ethers and lead scavengers in gasoline has been reduced or eliminated in recent years, these compounds may still be present at some older petroleum release sites (Weaver, et al., 2005, 2008, 2009; EPA, 2008).

Alternative fuels, especially those that contain higher percentages of ethanol present a challenge because ethanol readily biodegrades to create methane (Jewell and Wilson, 2011; Ma, et al., 2012 and 2014; Freitas, et al., 2010). The use of ethanol in motor fuels is increasing. Methane generation may be more significant at sites where large volumes of ethanol-blended gasoline (and higher ethanol content fuels, greater than E-20) have been released into the subsurface (Ma et al., 2014). Methane production can increase soil gas pressures and may result in advective soil gas flow toward receptors. In such situations, intrusion of methane into confined spaces may result in the accumulation of very high concentrations creating a risk of fire and explosion. In addition, methane also biodegrades under aerobic conditions and depletes oxygen that otherwise could be available for the biodegradation of PHCs. The depletion of oxygen may result in PHC vapors being transported farther than they otherwise would be, possibly increasing the threat of PVI.

---

[41] Aerobic biodegradation has been observed for the lead scavengers EDB (Prince and Douglas, 2010; Pignatello, 1986), and 1,2-DCA (Falta, 2004); the ethers MTBE (Prince and Douglas, 2010; Wang and Deshusses, 2007; Phelps and Young, 1999; Landmeyer and Bradley, 2003; Landmeyer, et al., 2010; Bradley and Landmeyer, 2006; Kuder, 2005; Lesser, et al., 2008; Baehr, Charles, and Baker, 2001) and Tertiary-amyl methyl ether (TAME) (Landmeyer, et al., 2010); the alcohols Ethanol (Powers, et al., 2001; Corseuil et. al, 1998), TBA (Wang and Deshusses, 2007; Landmeyer, et al., 2010), and Methanol (Powers, et al., 2001); and some organic lead compounds (Prince and Douglas, 2010; Gallert and Winter, 2004). Although anaerobic biodegradation is slower than aerobic biodegradation, anaerobic biodegradation may be a significant mechanism for destruction of non-PHCs fuel additives (and PHCs, especially in source areas.) Selected references on anaerobic biodegradation of various non-PHC fuel additives are listed under *Additional Information* at the end of this section.

Thus, separation distances that are usually protective against PVI may not be sufficiently protective in situations where methane is produced in large quantity (Ma et al., 2014). For additional information on sampling for the presence of methane, assessing potential risks, and how to manage the risks, see ASTM's "*New Practice for Evaluating Potential Hazard Due to Methane in the Vadose Zone*".[42]

Finally, in addition to the uncertainties regarding the rates of biodegradation of the lead scavengers EDB and 1,2-DCA,existing analytical methods are not able to detect them at very low concentrations representative of a cancer risk level of 1E-06. However, EPA (2013) suggests that although there are no soil gas data for lead scavengers in the PVI database, "a screening approach is feasible where groundwater concentrations are measured to determine the potential for vapor intrusion risks from EDB and 1,2-DCA." (see Section F.6). This approach is illustrated in the *Assessment* subsection through a sequence of equations and detailed discussion of the results for EDB and 1,2-DCA.

Assessment

Federal UST regulations (40 CFR 280.52(b)) stipulate that when conducting an investigation of a release from a regulated UST, investigators "must measure for the presence of a release where contamination is most likely to be present. In selecting sample types, sample locations, and measurement methods investigators must consider the nature of the stored substance, the type of initial alarm or cause for suspicion, the type of backfill, the depth of groundwater, and other factors appropriate for identifying the presence and source of release". Results of this sampling should also identify which contaminants should be assessed for potential vapor intrusion.

Once the candidate contaminants have been identified, the next step is to determine the target indoor air screening level for each of them. While the federal UST program does not prescribe human health values for contaminants, implementing authorities should use exposure values appropriate for the contaminants present and the characteristics of exposure (e.g., residential vs industrial). EPA provides a source of such exposure values in the Vapor Intrusion Screening Levels (VISL) Calculator.[43] VISLs for human health protection are generally recommended, medium-specific, risk-based screening-level concentrations intended for use in identifying areas or buildings that may warrant further investigation and mitigation as appropriate.

These VISLs are calculated and documented in the VISL Calculator and are based on:

---

[42] The new ASTM methane guide is accessible at http://www.astm.org/DATABASE.CART/WORKITEMS/WK32621.htm

[43] The VISL Calculator provides recommended, but not mandatory, screening levels for use in evaluating the vapor intrusion pathway at Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) and Resource Conservation and Recovery Act (RCRA) sites. The user's guide for the VISL Calculator provides additional information about derivation of the indoor air and subsurface screening levels (EPA, 2014a). Both the VISL Calculator (EPA, 2014b) and user's guide may be downloaded from EPA's website: http://www.epa.gov/oswer/vaporintrusion/guidance.html.

Current toxicity values selected considering OSWER's hierarchy of sources for toxicity values (EPA, 2003)[44]

- Physical-chemical parameters for vapor forming chemicals
- EPA recommended approaches for human health risk assessment

The VISLs include target indoor air screening levels for long-term (i.e., chronic) exposures that consider the potential for cancer and non-cancer effects of vapor-forming chemicals. The VISLs also include subsurface screening levels for comparison to sampling results for sub-slab soil gas, "near-source" soil gas, and groundwater. These subsurface screening levels are back-calculated from the target indoor air screening levels for chronic exposures using medium-specific, generic attenuation factors that reflect generally reasonable worst-case conditions (EPA, 2015, Appendix B). VISLs are not automatically response action levels, although EPA recommends that similar calculation algorithms be employed to derive cleanup levels (see EPA, 2015, Section 7.6 for more information).

The VISL Calculator allows users to specify an exposure scenario, target risk for carcinogens (TCR) and target hazard for non-carcinogens (THQ), and the average groundwater temperature at a site, and calculates screening levels for the target indoor air concentration, sub slab and exterior soil gas concentrations, and ground water concentration.

In the VISL Calculator, target indoor air concentrations are calculated using the equations presented in **Table 4**. For carcinogens, the inhalation unit risk (IUR) is the appropriate toxicity value. For non-carcinogens, the reference concentration (RfC) is the appropriate toxicity value. Each of these toxicity values is weighted by the appropriate exposure factors to determine the target indoor air screening concentrations. The smaller value (between $C_{ia,c}$ and $C_{ia,nc}$) is used as the target indoor air screening value.

Example calculations using the equations in **Table 4** are presented in **Table 5** for EDB and 1,2-DCA in indoor air under a residential exposure scenario. Note that the cancer screening levels ($C_{ia,c}$) are consistently lower than the non-cancer screening levels ($C_{ia,nc}$), thus the cancer screening levels would generally be used to assess risk to receptors for a given chemical.

[44] OSWER's toxicity data hierarchy is three-tiered. Tier 1 are values from EPA's Integrated Risk Information System (IRIS). The IRIS database is web accessible at *http://www.epa.gov/iris/*. Tier 2 are Provisional Peer Reviewed Toxicity Values (PPRTVs), which are accessible at *http://hhpprtv.ornl.gov/*. Tier 3 are "Other"sources, such as the Agency for Toxic Substances and Disease Registry (ATSDR), and various states (e.g., California (CA DTSC, 2009), Hawai'i (HI DOH, 2011, 2012), Massachusetts (MA DEP, 2009), New Jersey (NJ DEP, 2013), Washington (WA DEC, 2006). Links to these sources are provided under *References Cited* at the end of this section.) EPA's Regional Screening Levels (RSLs) for Superfund Sites compiles available toxicity information based on this hierarchy. The VISL Calculator draws on these RSL tables for toxicity values that are used to calculate VISLs. RSLs are accessible at *http://www.epa.gov/reg3hwmd/risk/human/rb-concentration_table/index.htm*.

Table 4. Equations For Target Indoor Air Screening Concentrations For Volatile Chemicals

Cancer	$C_{ia,c} = \frac{TCR \cdot ATc \cdot 365\ (days/year) \cdot 24(hours/day)}{EF \cdot ED \cdot ET \cdot IUR}$
Non-Cancer	$C_{ia,nc} = \frac{THQ \cdot RfC \cdot ATnc \cdot 365 \cdot 24 \cdot 1000(ug/mg)}{EF \cdot ED \cdot ET}$
$C_{ia,c}$ is the indoor air concentration for cancer risk, and $C_{ia,nc}$ is the indoor air concentration for non-cancer risk; the smaller value is used as the indoor air screening value. ATc and ATnc are the averaging times for cancer and non-cancer, respectively, and EF, ED and ET are exposure parameters (exposure frequency, duration, and time). The exposure factors should be consistent with those in Human Health Evaluation Manual, Supplemental Guidance: Update of Standard Default Exposure Factors OSWER Directive 9200.1-120 *http://www.epa.gov/oswer/riskassessment/pdf/superfund-hh-exposure/OSWER-Directive-9200-1-120-ExposureFactors.pdf*	

Table 5. Example Target Residential Indoor Air Concentrations For EDB And 1,2-DCA

Chemical	**$C_{ia,c}$ ($\mu g/m^3$)**	**$C_{ia,nc}$ ($\mu g/m^3$)**
1,2-Dibromoethane (EDB)	4.7E-03	9.4
1,2-Dichloroethane (1,2-DCA)	1.1E-1	7.3
Values (and units) of other variables used in these example residential calculations (equations in **Table 4**) are:		
Variable	Cancer (c)	Non-Cancer (nc)
IUR(c) or RfC(nc) (EDB)	6.0E-04 $(\mu g/m^3)^{-1}$	9 (mg/m^3)
IUR(c) or RfC(nc) (1,2-DCA)	2.6E-05 $(\mu g/m^3)^{-1}$	7 (mg/m^3)
TCR(c) or THQ(nc) (unitless)	10^{-6}	1.0
ATc or ATnc (years)	70	26
ED (years)	26	26
EF (days/year)	350	350
ET (hours/day)	24	24

After target indoor air screening levels (C_{ia}) have been established, the next step is to determine vapor source concentrations and assess whether these are high enough to potentially pose a threat of vapor intrusion. The equations in **Table 6** are used by the VISL Calculator to calculate groundwater and soil gas screening levels based on target indoor air screening levels. These groundwater and soil gas screening levels can then be compared to actual field measurements of groundwater and/or soil gas concentrations. If the measured concentrations are greater than the screening levels, then there is a potential for vapor intrusion, otherwise not.[45]

Table 6. Equations For Groundwater And Soil Gas Screening Levels Based On Target Indoor Air Screening Levels.

Ground Water Concentration	$C_{gw} = \frac{C_{ia}}{\alpha_{gw} \cdot 1000 \cdot HLC}$
Soil Gas Concentration	$C_{sg} = \frac{C_{ia}}{\alpha_{sg}}$

C_{ia} is the target indoor air screening level concentration (µg/m^3).
Cgw is the screening concentration in groundwater (µg/L).
Csg is the screening concentration in soil gas (µg/m^3).
HLC is the unitless Henry's Law constant.
α_{gw} and α_{sg} are the groundwater and soil gas vapor intrusion attenuation factors, respectively (both unitless).
1,000 is the number of liters per m^3 (to convert from units of µg/m^3 to µg/L).

[45] An individual subsurface sampling result that exceeds the respective, chronic screening level does not establish that vapor intrusion will pose an unacceptable human health risk to building occupants. Conversely, these generic, single-chemical VISLs do not account for the cumulative effect of all vapor-forming chemicals that may be present. Thus, if multiple chemicals that have a common, non-cancer toxic effect are present, a significant health threat may exist at a specific building or site even if none of the individual substances exceeds its VISL (see discussion of non-cancer hazard index in EPA (2015) Section 7.4.1).

These equations also may be rearranged to calculate a potential upper-bound indoor air screening concentration based on actual field measurements of groundwater and/or soil gas concentrations. For groundwater, the equation is rearranged like this:

$$(upper\ bound)C_{ia} = C_{gw} \cdot \alpha_{gw} \cdot 1000 \cdot HLC$$

Note that in order to calculate a screening level concentration in groundwater, a value for Henry's Law constant (HLC) is necessary.[46]

For soil gas the equation is rearranged like this:

$$(upper\ bound)C_{ia} = C_{sg} \cdot \alpha_{sg}$$

Appropriate values for the field measured concentration in groundwater or soil gas, and for the respective attenuation factors are plugged into the equation to yield an upper bound indoor air screening level for C_{ia}. The respective upper-bound indoor air screening level (derived from either groundwater or soil gas sampling data) is then compared to the target indoor air screening concentration (C_{ia}) from the VISL Calculator. If the upper-bound value is greater than the target value, then there is a potential for vapor intrusion, otherwise not (see Footnote #45).

In both cases, if there is a potential for vapor intrusion and where contamination is not in direct contact with an overlying building, then paired vapor samples should be collected to assess vapor attenuation. These paired samples should either be (a) near-slab (exterior) shallow soil gas samples paired with deep (source) soil gas samples, or (b) indoor air samples paired with sub-slab soil gas samples.

Table 7 presents example screening concentrations of EDB and 1,2-DCA in groundwater and soil gas using the equations in **Table 6**. These values represent the upper-bound concentrations according to Henry's Law that could be present in groundwater and soil gas, respectively, and not result in indoor air concentrations in excess of the target screening levels (i.e., VISLs) presented in **Table 5**. If concentrations measured in groundwater (C_{gw}) exceed these thresholds, it is possible that the target indoor air concentration will also be exceeded and mitigation may be necessary.

[46] The VISL Calculator is one source of Henry's Law constants. Because these constants are temperature dependent, the VISL Calculator automatically calculates the correct constant based on a temperature that is selected by the user.

Table 7. Example Screening Concentrations For EDB And 1,2-DCA In Groundwater And Soil Gas

Chemical	C_{gw} (µg/L)	C_{sg} (µg/m^3)
1,2-Dibromoethane (EDB)	0.18	.16
1,2-Dichloroethane (1,2-DCA)	2.2	3.7
Target residential indoor air concentrations ($C_{ia,c}$) are from **Table 5**. Selected attenuation factors (α) are 0.001 for groundwater and 0.03 for soil gas. These are taken from the VISL Calculator and do not account for biodegradation. Dimensionless Henry's Law constants (HLC) for groundwater at 25°C are 0.0266 for EDB and 0.048 for 1,-DCA. These values are also taken from the current version of the VISL Calculator.		

The lead scavengers present an additional challenge in that existing analytical methodology is not able to detect them at very low concentrations representative of a cancer risk level of 1E-06 for either EDB or 1,2-DCA. As shown in **Table 8**, Selective Ion Monitoring (SIM) is able to achieve a detection limit representative of the 1.0E-04 risk level for EDB and 1.0E-05 for 1,2-DCA. Commercial low level is able to achieve a detection limit representative of the 1.0E-05 risk level for 1,2-DCA. However, an analytical detection limit does not impact the risk level for a certain chemical. The chemical may be present at a concentration greater than the appropriate risk level concentration, but below the limit of detection, which may result in undetected risk to potential receptors. Approaches to compensate for such analytical limitations include using available modeling data and professional judgment to evaluate whether the chemical may be present and having samples reanalyzed by special analytical services. For the screening level assessment, the chemical should be carried through assuming that it is present at the concentration equivalent to the quantitation limit. This allows the risk at the quantitation limit to be compared to the risks associated with other chemicals at the site. At minimum, the chemical should be addressed qualitatively. These topics are beyond the scope of this PVI guide; additional information may found in EPA's *Risk Assessment Guidance for Superfund* (RAGS).[47]

[47] The *Risk Assessment Guidance for Superfund (RAGS)* document is accessible at http://www.epa.gov/oswer/riskassessment/ragsa/index.htm. In particular see Section 5.3 in Part A, and Part F: Supplemental Guidance for Inhalation Risk Assessment.

Table 8. Comparison Of Risk Levels And Achievable Analytical Detection Limits For The Lead Scavengers EDB And 1,2-DCA In Indoor Air.

Compound	Target Indoor Air Concentration			Analytical Method		
	Risk Level 1.0E-04	Risk Level 1.0E-05	Risk Level 1.0E-06	Commercial conventional	Commercial low level	Commercial SIM
EDB	0.47	0.047	0.0047	3.8	0.77	0.23
1,2-DCA	11	1.1	0.11	2.0	0.40	0.12

NOTE: all values in $\mu g/m^3$
1.0E-04 = increased lifetime cancer risk of 1 per 10,000
1.0E-05 = increased lifetime cancer risk of 1 per 100,000
1.0E-06 = increased lifetime cancer risk of 1 per 1,000,000
Commercial conventional = EPA Method TO-15 (see http://www.epa.gov/ttn/amtic/files/ambient/airtox/to-15r.pdf)
Commercial low level = EPA Method TO-15 (modified)
SIM = Selective Ion Monitoring
The achievable detection limits in this table are representative of the general state of the technology as of the present date. Some laboratories may be able to achieve lower detection limits using modified techniques. Future technological improvements may also result in lower detection limits.
Achievable
Not Achievable

Special Considerations

VISL Calculator screening levels do not include the effects of biodegradation on the concentrations of vapors in soil that could potentially intrude into indoor air. The generic attenuation factors used in calculating VISLs (i.e., 0.001 for groundwater, 0.03 for soil gas) are conservative, and may overestimate the transfer of some contaminants (e.g., those that biodegrade aerobically) from soil gas to indoor air in some buildings. As a result these screening levels will usually overestimate the true indoor air concentrations of aerobically-biodegradable volatile contaminants (e.g., PHCs). Decision-makers may choose to use alternate approaches (e.g., attenuation factors that account for biodegradation) that may be more appropriate for specific sites where circumstances do not match the underlying assumptions used in calculating the VISLs.

When Information is available on the separation distance between the source of contamination and the receptor, on the total concentration of biodegradable compounds in soil gas, and on the rate constant for degradation of contaminant vapors in soil, it is possible to refine the estimate of the attenuation factor (α) between soil gas and indoor air for some VOCs and PHCs. Approaches to refine the estimate of the attenuation factor (α) for PHCs are discussed in **Section 12** (p.100) and by Wilson et al. (2014). Also see **Section 13** (p.106) for information on the use of models to estimate attenuation factors. However, until more is known about the rates of biodegradation of EDB and 1,2-DCA in soil gas, the separation distances for PHCs shown in Section 5 and the approaches described in **Section 12** or **Section 13** for determining attenuation factors are not recommended for these two contaminants.

In addition to concerns discussed earlier, other potential concerns with increasing ethanol content are in relation to (re)mobilization of LNAPL (McDowell, et al., 2003; Yu, et al., 2009) and increased solubility of PHCs (Powers, et al., 2001). The implications of these impacts may extend beyond vapor intrusion; see **Section 7** (p.61) for information about LNAPL and **Section 6** (p.57) for information about dissolved contaminant plumes.

Recommendation

EPA recommends that groundwater samples be analyzed for PHCs and non-PHC fuel additives (e.g., alcohols, ethers, organic lead, lead scavengers) typically found in petroleum-based fuels, when appropriate. At the present level of knowledge, the groundwater and soil gas screening levels in **Table 7** are the best values to use to determine whether indoor air target levels will be exceeded for EDB and 1,2-DCA. If measured concentrations of EDB and 1,2-DCA in groundwater exceed the screening levels in **Table 7**, EPA recommends gathering additional information and data to determine whether mitigation is appropriate. The methodology illustrated in the *Assessment* subsection above can be applied to any non-PHC (or any VOC for that matter) for which an appropriate toxicity value and attenuation factor are available.

11. Seasonal And Weather Effects

Description

The generation and movement of petroleum vapors are subject to seasonal effects such as temperature trends and fluctuations; and weather effects such as precipitation, barometric pressure changes, and wind (Lundegard, Johnson, and Dahlen, 2008). Cycling of heating and cooling systems inside buildings in response to seasonal and weather effects may also influence vapor intrusion.

Importance

Biological processes slow down with decreasing temperatures, though microorganisms continue to biodegrade PHCs at environmentally significant rates even when temperatures are near freezing (Bradley and Chapelle, 1995; Bradley, Richmond, and Chapelle, 2005; Hers, et al., 2011). Bradley and Landmeyer (2006) documented microbial degradation of MTBE in the wintertime when groundwater temperatures were below 5˚C.

There is conflicting evidence as to whether, and under what additional conditions, frozen or ice-covered soil reduces the movement of oxygen into the subsurface. Hers, et al. (2011) studied a residential site in Canada where subsurface oxygen readings taken throughout the winter did not indicate a decrease in oxygen content of soil gas and there was evidence that biodegradation was occurring. However, the residence was above a crawl space and the soil below the house was never covered by ice or snow. It is known that the air permeability of a snow layer is a complex function of pore size, grain size, ice fraction, and density (Armstrong, 2008; Bender, 1957; Conway and Abrahamson, 1984). Rike (2003) observed ongoing biodegradation in frozen arctic soils. In that study, a lengthy period of subfreezing soil temperatures at a petroleum contaminated site did not result in decreasing oxygen concentrations. In contrast, Freyman (1967) and Yanaia (2010) report that oxygen depletion has been observed in other studies of soils under ice sheets and snow cover. More study is needed to resolve this issue.

Precipitation events can impact biodegradation of petroleum vapors. A certain amount of soil moisture is necessary for microorganisms to live; not enough and they are not actively degrading PHC vapors; too much and reoxygenation is impeded, possibly leading to anaerobic conditions at greater depths (Silver, 1999; Ludemann, 2000; Pezeschki, 2001). Wind and barometric pressure changes can produce pressure gradients inside buildings. Negative pressure inside buildings can result in enhanced intrusion of PHC vapors. Positive pressure inside buildings can both prevent intrusion of PHC vapors into buildings and facilitate oxygen transport through cracks in the foundation into the subsurface. This can result in reoxygenation of the soil beneath the building that would otherwise be depleted of oxygen (Lundegard, Johnson, and Dahlen, 2008).

Heating systems in buildings, which operate most frequently during winter months, can create a chimney effect, whereby PHC vapors are pulled into buildings at much higher rates than they would ordinarily. Cooling systems, which operate only during summer months, can have the opposite effect, creating positive pressure gradients in basements that both prevent intrusion of PHC vapors into buildings and allow oxygen to enter the soil (Lundegard, Johnson, and Dahlen, 2008).

Assessment

Seasonal and weather conditions can influence the characteristics of PHC vapor migration over time. Data on temporal changes in temperature, barometric pressure, wind speed and direction, relative humidity, and precipitation can aid in correctly identifying trends and result in a more accurate CSM.

In addition, site characteristics that may indicate susceptibility to the effects of seasonal and weather factors should be assessed. These include:

- Poor drainage around the building indicated by flooded soils
- Area subject to permafrost/long lasting snow cover (based on altitude or latitude)
- Shallow and highly variable water table

Special Considerations

Seasonal effects may also influence the formation and migration of dissolved plumes and LNAPL. Changes in water table elevation can create a smear zone of residual LNAPL contamination. LNAPL in the smear zone can act as a long-term source of dissolved contamination during periods of high water table elevation and as a source of petroleum vapors during periods of low water table elevation when contaminants reemerge from a previously submerged condition. Groundwater levels in the vicinity of USTs may also be subject to the influence of water within the tank pit. After rainfall events (and potentially snowmelt) water levels within tank pits are typically above the level of ambient groundwater; consequently a groundwater recharge mound may form. This mound disrupts the local groundwater flow field and contaminants can migrate away from the tank excavation, potentially in all directions.

Recommendation

During site characterization activities, weather conditions such as temperature, barometric pressure, and wind speed/direction should be recorded to aid in recognizing the cause of trends or anomalies in the PVI data and not merely attributed to unknown factors. This information may be obtained from the National Oceanic and Atmospheric Administration (NOAA) (see *http://www.noaa.gov/wx.html*) or a nearby airport where weather data are recorded hourly.

12. Vapor Intrusion Attenuation Factor (α)

Description

When Johnson and Ettinger (1991) published their vapor intrusion model they introduced a parameter to relate the vapor concentration of a volatile chemical inside a building to its vapor concentration at the subsurface source. The parameter, designated alpha (α), is also called the vapor intrusion attenuation factor. It is defined mathematically as the concentration in indoor air divided by the concentration in soil gas at the source (with concentrations in the same units). The source is defined as the region of highest vapor concentration in the vadose zone. Large values of α (i.e., values approaching one) indicate that little attenuation is taking place, whereas small values of α (i.e., values much smaller than one) indicate that significant attenuation is taking place.

Importance

As part of a risk evaluation, the concentrations of a chemical in indoor air can actually be measured, or they can be predicted. The attenuation factor is used as a part of a risk evaluation to predict or estimate the concentration of a chemical in indoor air from the concentration measured in soil gas below or near a building. To predict the indoor air concentration, the measured concentration in soil gas is multiplied by the suitable attenuation factor.

Assessment

U.S. EPA (2013, Table 6-1) provides recommended vapor attenuation factors for risk-based screening of the vapor intrusion pathway for residential buildings. For example, the generic values of α in EPA (2015) are 1.0E-03 (0.001) for groundwater, 3.0E-02 (0.03) for sub-slab soil gas, and 3.0E-02 (0.03) for deep (near-source) soil gas. These values of α are derived from measurements made during case studies of the vapor intrusion of chlorinated solvents such as trichloroethylene (TCE), which are not biologically degraded in aerobic unsaturated soil or sediment. Likewise, values for concentrations in indoor air that are derived from the model of Johnson and Ettinger (1991) also do not include any consideration of biodegradation. As a result, the generic values of α in U.S. EPA (2015) and values for indoor air that are calculated using the Johnson and Ettinger model (JEM) overestimate the indoor air concentrations of PHCs. Thus, these values of α are not applicable to PVI from leaking USTs.[48] For additional information on estimation of sub-slab attenuation factors, see Brewer et al. (2014).

To provide estimates of α that are more suitable for PHCs, Abreu, Ettinger, and McAlary (2009) developed a three-dimensional computer model to predict the effects of biodegradation in the unsaturated zone below a building on the concentrations of chemicals in the indoor air of the building. They performed a series of model simulations to estimate semi-generic values of α from site-specific information on the vertical separation distance between the receptor building

[48] Attenuation factors that account for biodegradation can be derived from models such as *BioVapor* or *PVIScreen* (see **Section 13**, p.106 for more information). Additional guidance may be found in Wilson *et al.* (2014).

and the source, and the total concentration of biodegradable compounds in soil gas at the source of the hydrocarbons. **Figure 9** compiles the computer simulations conducted by Abreu, Ettinger, and McAlary (2009) of the attenuation factor during vapor intrusion into a building with a basement. This figure presents the concentration of biologically degradable hydrocarbon in an unconventional unit (mg/L as benzene).

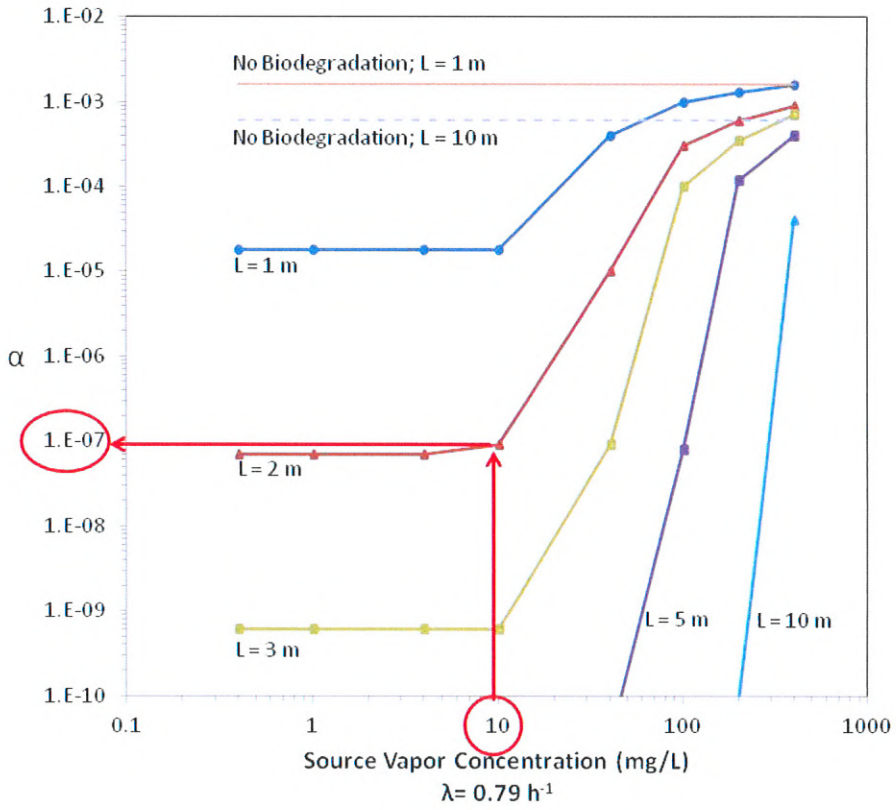

Figure 9. Relationship Between Source Vapor Concentration And Vapor Intrusion Attenuation Factor (α) As A Function Of Vertical Separation Depth Between Contaminant Source And Base Of Building (Receptor) (Source: modified from Abreu, Ettinger, and McAlary, 2009, Figure 7, page 114. Reprinted from *Groundwater Monitoring & Remediation* with permission of the National Ground Water Association. Copyright 2009.)

To generate **Figure 9**, Abreu, Ettinger, and McAlary (2009) used conservative assumptions for the rate of biodegradation. In this particular set of simulations, the first order rate constant for biodegradation (λ) was set at 0.79 h^{-1}, a reasonable average rate based on the range of rates published in the literature (DeVaull 2007). Model simulations assume the building has a basement and that it is surrounded by homogeneous, uniform sandy soil that is directly exposed to the atmosphere and that preferential pathways for vapor migration into the building or through the vadose zone are not present. As a result, the concentration of oxygen

in the soil gas in the topmost layer of exposed soil is the concentration of oxygen in the atmosphere. Compared to silty or clayey soils, sandy soils have more air filled porosity and as a result, vapors diffuse more rapidly through them (and they also allow more oxygen to diffuse from the atmosphere). The simulations assumed that the square building was 10 meters (33 feet) on each side.

Figure 9 can be used to estimate the value of α for situations where the total concentration of vapors at the source and the vertical separation distance between the contaminant source and the bottom of the building are known and all of the other input parameters match site conditions. For example, for a source vapor concentration of 10 mg/L and a vertical separation distance (L) of 2 meters (6.6 feet), the estimated value of α would be approximately 1.0E-07. To complete the exposure assessment, the measured concentration of benzene in soil gas at the source of contamination is multiplied by the value of α, to predict the indoor air concentration in a building.

Figure 10 is a redraft of **Figure 9**, where the source concentration of vapors is expressed in more conventional units for vapors in soil gas ($\mu g/m^3$). The oxygen demand of all the hydrocarbons that might be in soil gas is expressed as the concentration of TPH (gasoline) plus the concentration of methane. The concentration of TPH (gasoline) can be determined by modified EPA Method TO-15 (see *http://www.epa.gov/ttn/amtic/files/ambient/airtox/to-15r.pdf*) referenced to heptane. The concentration of methane can be determined as a fixed gas or by EPA Method 3C. The concentration of methane is multiplied by 1.136 to correct for the differences between the theoretical oxygen demand of methane and heptane.

Special Considerations

Figure 9 or **Figure 10** should only be used for UST sites with the same characteristics that were simulated by Abreu, Ettinger, and McAlary (2009). These conditions were relatively conservative. **Figure 9** and **Figure 10** are not appropriate for use at sites where the oxygen flux from the surface is impeded.

Some documents define the vapor intrusion attenuation factor differently than defined by Johnson and Ettinger (1991) and discussed in this section. The JEM (see **Section 13**, p.106) ignores background sources when estimating the indoor air concentration arising from vapor intrusion. When used in this PVI guide, the Greek letter alpha (α) refers strictly to attenuation during vapor intrusion, which might be observable if there were no background (ambient) vapor sources. In contrast, some empirical attenuation factors (sometimes designated *AF*) are based on indoor air concentrations that include both background sources and vapor concentrations that intrude into the building from a subsurface vapor source. Thus, when there is a measurable contribution from an ambient source, an attenuation factor such as *AF* (which includes the contribution of ambient sources) would be somewhat greater than the Johnson & Ettinger alpha (α), which would indicate less attenuation than is actually occurring.

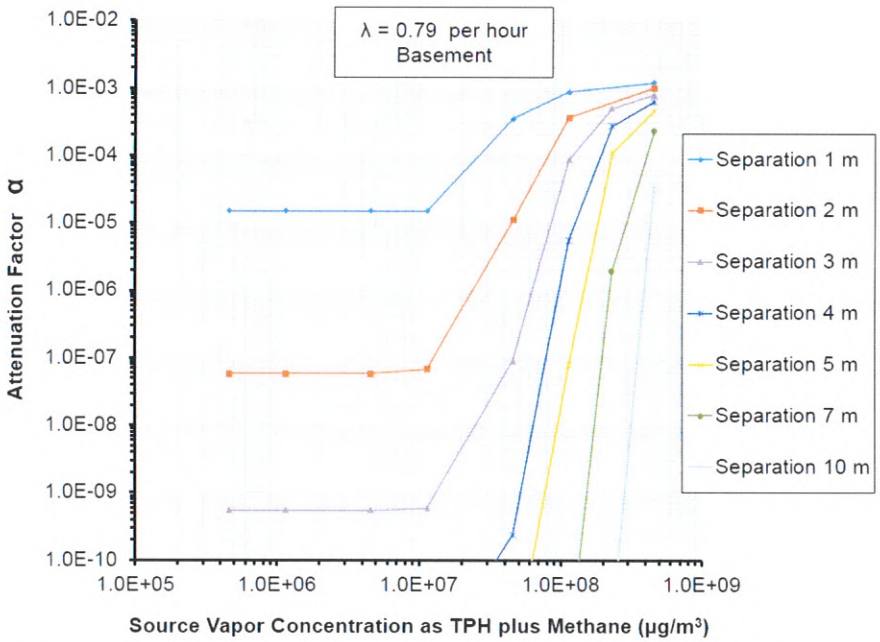

Figure 10. Rescaled Figure 9 That Expresses The Source Vapor Concentration In Conventional Units.

Recommendation

When evaluating the vapor source and attenuation of PHC vapors, paired vapor samples are required to measure the actual attenuation that occurs due to aerobic biodegradation. Where contamination is not in direct contact with an overlying building, choose one of two options: (1) collect near-slab (exterior) shallow soil gas samples paired with deep (source) soil gas samples, or (2) collect indoor air samples paired with sub-slab soil gas samples. Note that for option 2 if the measured concentration of vapor in indoor air is below the applicable allowable indoor concentration there is no need to measure sub-slab vapor concentration. If contamination is in direct contact with a building basement, foundation, or slab, it is necessary to collect indoor air samples as it will not be feasible to collect sub-slab vapor samples. If a generic vapor intrusion attenuation factor and the measured concentration of a PHC in shallow soil gas predict an acceptable concentration in indoor air, that prediction may be adequate to support a screening decision. However, generic attenuation factors may not be appropriately representative of conditions at a particular site.

Models may provide better estimates of α, but only if the actual conditions at a specific site match the assumptions of a particular model. For biodegradable PHCs it would be better to implement a transport and fate model that is designed to simulate the contribution of biodegradation. The three-dimensional models of Abreu, Ettinger, and McAlary (2009) and Verginelli and Baciocchi (2014) are potential options. BioVapor, a model developed by the American Petroleum Institute, is another option. U.S. EPA is developing a model called PVIScreen that is intended for this purpose. See **Section 13** (p.106) for more discussion of the appropriate use of computer models for PVI investigations.

13. Computer Modeling Of Petroleum Vapor Intrusion

Description

A number of models have been developed and applied in estimating transport of volatile chemicals from subsurface soil and groundwater to indoor air (Bekele, et al. 2013). Lahvis (2011) presents a summary of 35 different analytical screening-level models, including a discussion of features, and assumptions. Models generally used for simulation of PVI are either the Johnson-Ettinger model (JEM) or BioVapor.

Johnson-Ettinger Model (JEM)

Johnson and Ettinger introduced one of the first vapor intrusion models in 1991. This model is referred to as the Johnson-Ettinger Model or JEM. Features of the JEM include:

- A steady or transient source of subsurface vapors from groundwater or residual chemicals
- Gaseous-phase diffusive vapor flow through a layer of soil
- Vapor transport through a slab-on-grade or basement foundation
- Building air exchange

The JEM presumes that the concrete foundation is impermeable and vapor movement occurs only through cracks and other openings. However, concrete is permeable to vapors and gases. Effective diffusion rates for intact air-dry concrete have been measured for hydrocarbons, oxygen, methane, and radon with an overall measured range from 1.08 to 15.6 cm^2/hr (Haghighat, et al., 2002; Patterson and Davis, 2009; Kobayashi and Shuttoh, 1991; Tittarelli, 2009; Yu, et al., 1993). Thus, diffusive vapor flow for typical foundation areas and thicknesses can be significant (McHugh, de Blanc, and Pokluda, 2006; Luo, et al., 2012). Actual measurement of differential pressure across varied building foundations show a significantly variable component over time (Nazaroff, et al., 1985; Hintenlang and Al-Ahmady, 1992; Robinson, et al., 1997a,b; McHugh , de Blanc, and Pokluda, 2006; Lundegard, Johnson, and Dahlen, 2008; Patterson and Davis, 2009; Luo and Johnson, 2011).

For sites where PHCs are present and aerobic biodegradation of PHCs occurs in the vadose zone, comparisons to JEM consistently show the model to over-predict indoor air concentrations by at least several orders of magnitude (Fitzpatrick and Fitzgerald, 2002; Sinke, 2001; Ririe, Sweeny, and Daugherty, 2002; Hers, et al., 2003; Davis, 2006; Golder Associates, 2008; Davis 2009). The potential for over-prediction is greatest for sites with low concentrations of PHCs in soil and groundwater (API, 2009; Davis, 2009; Energy Institute, 2009).

The original model has been revised numerous times to attempt to account for biodegradation, which was not included in the original JEM (see Johnson, Kemblowski, and Johnson, 1998; Ririe, et al., 1998; Johnson, Hermes, and Roggemans, 2000; Spence and Walden, 2010; Parker, 2003; Environmental Systems and Technologies, 2004; DeVaull, 2007a; Mills, et al., 2007; Turczynowicz and Robinson, 2007; API, 2010; Lahvis, 2011). EPA also revised the original JEM.

The most current information on EPA's revised model may be found on EPA's website at http://www.epa.gov/oswer/riskassessment/airmodel/johnson_ettinger.htm.

BioVapor

The BioVapor model (DeVaull, 2007a; API, 2010) is a Microsoft Excel© macro that uses a conceptual model similar to the JEM. BioVapor includes the following features:

- A steady subsurface petroleum vapor source.
- Gaseous-phase diffusive vapor flow through a layer of soil.
- Vapor transport through a slab-on-grade or basement foundation.
- Building air exchange.

In contrast to JEM, BioVapor accounts for oxygen-limited, aerobic biodegradation. Aerobic biodegradation is included as a coupled reaction between petroleum vapors and oxygen. Oxygen availability in the subsurface is dictated by transport through and around the building foundation, and by diffusion into the soil. The BioVapor model requires estimates of chemical-specific aerobic degradation rates for vadose zone soils. DeVaull (2007a,b) provides default values based on measured data. DeVaull (2011) provides improved estimates of both median values and observed ranges for an expanded set of specific chemicals.

PVIScreen

PVIScreen (Weaver, 2015) is based on the equations of BioVapor but is coded in Java to improve computational efficiency and allow for implementation of algorithms to automate uncertainty analysis. Most computer models must be run multiple times with varying input parameters in order to conduct a typical sensitivity analysis. PVIScreen automates this function by treating input variables as ranges and then conducting a Monte Carlo analysis. The results, which are provided in a matter of seconds, are presented as the probability that the indoor air concentration is less than a risk-based level. This is in contrast to most models that provide single values for various output parameters. PVIScreen also allows for flexible unit choices and presents results in an automatically-generated report.

Importance

Vapor intrusion models that include oxygen limited biodegradation support development of petroleum-specific exclusion distance criteria (i.e., lateral inclusion zone—see **Section 4**, p.44; vertical separation distance—see **Section 5**, p.48). Model results are consistent with empirical exclusion distance values derived from several PVI field investigations. These include Lahvis, et al. (2013); Davis (2009); Peargin and Kolhatkar (2011); Wright (2011); McHugh, et al. (2010), and Verginelli and Baciocchi (2014). Site assessment and field data including the depth to contamination, source strength, and type (LNAPL or dissolved) are key parameters for determining these exclusion distance criteria.

Estimates using the BioVapor model indicate that for moderate or weak sources (especially dissolved plumes), biodegradation effectively eliminates the potential for PVI. Conversely, where vapor sources are both high in concentration and in close proximity to the bottom of a foundation, the BioVapor model predicts significant potential for PVI.[49] Notably, in these cases the BioVapor model predicts significantly higher potential for PVI below a foundation, where oxygen availability is more limited, than adjacent to the foundation where the soil surface is open to air and oxygen availability is greater. This prediction is consistent with measured vertical profiles of hydrocarbons and oxygen for high concentration vapor sources taken both below a foundation and beside a foundation (Patterson and Davis, 2009; Laubacher, et al., 1997).

Weaver (2012) presents results of a sensitivity analysis that indicates when biodegradation occurs, it dominates the other processes included in the BioVapor model. In these cases, the parameters representing aerobic biodegradation, source depth, and source strength dominate the model results. In the other cases where biodegradation is insignificant, building parameters become more important, as they are in the JEM (Tillman and Weaver, 2007).

More complex numerical models including oxygen-limited biodegradation have been developed and applied. Abreu and Johnson (2006) present results for a three-dimensional model. With matched model parameters, there is reasonable agreement between the three dimensional results and those predicted with the BioVapor model (DeVaull, 2007b) and PVIScreen (Weaver, 2015). Each of these model results show similar sensitivities to changes in model parameters, and support the use of exclusion distances such as those recommended in this document (see **Section 4**, p.44, lateral inclusion zone, and **Section 5**, p.48, vertical separation distance).

Assessment

When selecting an appropriate computer model, the mathematical formulation needs to be consistent with conditions at the site and the CSM. If the computer model is not matched to conditions at the site, then error is likely introduced into the computer model results. This means that input parameters for the computer model should be representative of the actual physical, chemical, and biological properties of the site. Typically all factors influencing vapor intrusion are not included in currently available models. Even with more advanced modeling, resource limitations would prevent the detailed characterization necessary to determine representative values for some of the input parameters. Some of these factors include subsurface heterogeneity, variation in building operation, subsurface moisture content, variations in weather and others. For most other types of environmental models, limitations in characterization are mitigated by calibration to known endpoints, typically concentration distributions. Though calibration results may not be unique (that is the same results could potentially be obtained using different values for the same suite of input parameters), when these results match field conditions, a model is deemed to be useful for predictive simulations.

[49] Moderate or weak sources are associated with dissolved plumes. Strong sources are associated with LNAPL. **Table 3** on page 52 presents concentration thresholds associated with dissolved plumes and LNAPL.

Special Considerations

Most of the parameters describing model processes will not be known with certainty. A common limitation is that field measurements of all the input parameters (e.g., biodegradation rates, soil moisture content beneath buildings, air exchange rates) are typically not available, and those that are (e.g., source concentration) may be spatially or temporally variable. Literature values are typically substituted for site-specific data. This leads to uncertainty as to whether parameter values are truly representative of site conditions. Model results will likewise inevitably lack certainty (Bekele, et al, 2013). The importance of these (and other) parameters is determined through an uncertainty analysis. By determining the impact of parameter variability on the model results, the uncertainty analysis adds confidence to the conclusions drawn from the model.

Recommendation

An appropriate framework for the use of a mathematical model and understanding of model characteristics is critical when using the results of mathematical models for regulatory purposes (Hers, et al., 2003). The appropriate role for a model in a PVI investigation is as a means to explain observed behavior. EPA recommends the use of a model that considers aerobic biodegradation when assessing the potential for PVI. Regardless of which model is used to simulate PVI, EPA recommends that an uncertainty analysis be conducted to provide error bounds on predictions of the computer model.

Model results obtained by using site-specific inputs can provide results that inform decision-making. In particular, model results can be used to demonstrate that: sufficient oxygen exists to degrade petroleum contaminants, contaminant vapor distributions are plausible given conditions at the site, estimates of the vapor attenuation anticipated in the subsurface due to biodegradation are reasonable. Models may also be used for purposes such as improving a site-specific sampling strategy, validation (or refutation) of the CSM by comparing a model to measured soil gas data, and in estimating the effect of varied or changed site conditions (e.g., including construction of a new building on a brownfields site).

Model results can thus be used as one line of evidence that a building is not likely to be impacted by PHC vapors. At the present time and state of knowledge, EPA cautions that model results should not be used as the sole rationale for determining that a building is not threatened or impacted by PVI.

Glossary

Note: Most of these definitions are from EPA's on-line glossaries (see http://iaspub.epa.gov/sor_internet/registry/termreg/searchandretrieve/termsandacronyms/search.do).

Absorption: the penetration of atoms, ions, or molecules into the bulk mass of a substance. In contrast, adsorption is the retention of atoms, ions, or molecules onto the surface of another substance

Advection: the process of transfer of fluids (vapors or liquid) through a geologic formation in response to a pressure gradient that may be caused by changes in barometric pressure, water table levels, wind fluctuations, or infiltration

Aerobic: able to live, grow, or take place only when free oxygen is present

Anaerobic: able to live, grow, or take place where free oxygen is not present

Analyte: the element, ion, or compound that an analysis seeks to identify; the element of interest

Attenuation: the reduction or lessening in amount (*e.g.*, a reduction in the amount of contaminants in a plume as it migrates away from the source)

Biodegradability (or biodegradation potential): the relative ease with which organic chemicals will degrade as the result of biological metabolism. With respect to petroleum hydrocarbons, although virtually all petroleum hydrocarbons are biodegradable, biodegradability is highly variable and dependent somewhat on the specific type of hydrocarbon. In general, biodegradability increases with increasing solubility; solubility is inversely proportional to molecular weight.

Biodegradation: a process by which microbial organisms transform or alter (through metabolic or enzymatic action) the structure of chemicals introduced into the environment

Biologically active soil: in the context of a PVI investigation means that the subsurface soil environment will support populations of microorganisms that are present in sufficient quantities to aerobically degrade PHC vapors before they intrude into a receptor. Effective aerobic biodegradation of petroleum hydrocarbons depends on the soil having sufficient oxygen and enough soil water to provide a habitat for adequate populations of active microorganisms. The presence of sufficient oxygen must be determined by the collection and analysis of soil gas. Soil that is too dry will not support microbial life. The soil generally will not be too dry for bacteria if the depth to the water table is less than 300 feet, or if the soil around the receptor supports the growth of plants characteristic of temperate climates. (NOTE that in hot, arid climates lack of soil moisture may inhibit biodegradation of PHCs) Concentrations of carbon dioxide which are ten-fold higher than concentrations in the atmosphere are an acceptable indication that conditions support microbial respiration. The actual habitat of soil bacteria is the thin film of water held to the surface of soil particles by capillary attraction. Coarse sand and gravel with a low content of silt or clay or organic matter, or fractured consolidated rock, or consolidated rock with solution channels, may not have enough soil water in intimate contact with soil gas to support adequate densities of biologically active microorganisms. These geological materials do not qualify as "biologically active soil."

BTEX: acronym for the aromatic hydrocarbons benzene, toluene, ethylbenzene, and xylenes (three isomers)

Capillary fringe: the zone of a porous medium above the water table within which the porous medium is saturated by water under pressure that is less than atmospheric pressure. See also *vadose zone* and *unsaturated zone*.

Clean monitoring point: Concentration thresholds for "clean" monitoring points are: the BTEX concentration in groundwater is equal to or less than the respective maximum contaminant level (e.g., 5 µg/L for benzene); the TPH concentration in soil is less than 20 mg/Kg; there is no potential presence of liquid or residual phase LNAPL; the oxygen concentration is greater than 0.2 percent; and the combustible gas concentration in soil gas is less than 100 ppm (v/v).

Clean soil: In the context of a PVI investigation, clean soil does not necessarily mean that the soil is free from all contamination, but rather that any contamination present is at concentrations low enough that the biological activity of the soil is sufficient to biodegrade PHC vapors before they reach a receptor.

Computer model: a mathematical representation of a physical process or system. Computer models are based upon sound conceptual site models to provide meaningful information. As the complexity of computer models increases, so does the amount of data required, and the quality of the output from computer models is directly related to the quality of the input data. Because of the complexity of natural systems, models necessarily rely on simplifying assumptions that may or may not accurately represent the dynamics of the natural system. Calibration and sensitivity analyses are important steps in the appropriate use of models.

Conceptual site model (CSM): a three-dimensional representation that conveys what is known or suspected about potential contamination sources, release mechanisms, and the transport and fate of those contaminants. The conceptual model provides the basis for assessing potential remedial technologies at the site. "Conceptual site model" is not synonymous with "computer model"; however, a computer model may be helpful for understanding and visualizing current site conditions or for predictive simulations of potential future conditions.

Contamination: in the context of a PVI investigation, contamination means that: the BTEX concentration in groundwater is greater than the respective MCL; or the TPH concentration in soil is greater than 100 mg/Kg; or there is potential presence of liquid or residual phase LNAPL; or the combustible gas concentration in soil gas is greater than 100 ppm (v/v).

Diffusion: the process by which molecules in a single phase equilibrate to a zero concentration gradient by random molecular motion (Brownian motion). The flux of molecules is from regions of high concentration to low concentration and is governed by Fick's Second Law.

Dispersion: the process by which a substance or chemical spreads and dilutes in flowing groundwater or soil gas

Downgradient: in the direction of decreasing potentiometric head; the general direction of groundwater flow

First responder: refers to those individuals who in the early stages of an incident are responsible for the protection and preservation of life, property, evidence, and the environment. Typically these are police, firefighters, or emergency medical personnel.

Fixed gases: refers to the gases nitrogen, oxygen, argon, carbon dioxide, and carbon monoxide. The volume of these gases together accounts for virtually 100 percent of the composition of the earth's atmosphere. Presence and concentration of these gases are determined using gas chromatography (GC).

Flux: the rate of movement of mass through a unit cross-sectional area per unit time in response to a concentration gradient or some advective force

Free product: a petroleum hydrocarbon in the liquid ("free" or non-aqueous) phase (see also light non-aqueous phase liquid, LNAPL)

Gradient: the rate of change in value of a physical or chemical parameter per unit change in position For example, hydraulic gradient is equal to the difference in head measured at two points (usually wells) divided by the distance separating the two points. The dimensions of head and distance are both lengths, therefore the gradient is expressed as a dimensionless ratio (L/L).

Groundwater: the water contained in the pore spaces of saturated geologic media

Henry's law constant: the ratio of the concentration of a compound in air (or vapor) to the concentration of the compound in water under equilibrium conditions

Henry's law: the relationship between the partial pressure of a compound and the equilibrium concentration in the liquid through a proportionality constant known as the Henry's law constant

Heterogeneous: varying in structure or composition at different locations in space

Homogeneous: uniform in structure or composition at all locations in space

Hydraulic gradient: the change in total potentiometric (or piezometric) head between two points divided by the horizontal distance separating the two points

Hydrocarbon: chemical compounds composed only of carbon and hydrogen

Inclusion zone: the area surrounding a contaminant mass through which vapor-phase contamination may travel and intrude into buildings and potentially result in adverse health effects to inhabitants

Indian country: (1) All land within limits of any Indian reservation under the jurisdiction of the United States government, notwithstanding the issuance of any patent, and, including rights-of-way running through the reservation; (2) All dependent Indian communities within the borders of the United States whether within the original or subsequently acquired territory thereof, and whether within or without the limits of a state; and (3) All Indian allotments, the Indian titles to which have not been extinguished, including rights-of-way running through the same.

Indigenous: living or occurring naturally in a specific area or environment; native

Isotropic: the condition in which hydraulic properties of an aquifer are equal when measured in any direction

Lateral inclusion zone: the area surrounding a contaminant mass and for which all buildings within its boundaries should be assessed for potential PVI. By definition, all buildings that overlie contamination in any phase are within the lateral inclusion zone.

Light non-aqueous phase liquid (LNAPL): contaminants that remain as the original bulk liquid with a density less than that of water (see also free product)

Microorganisms: microscopic organisms including bacteria, protozoans, yeast, fungi, mold, viruses, and algae

Permeability: a qualitative description of the relative ease with which rock, soil, or sediment will transmit a fluid (liquid or gas). Often used as a synonym for hydraulic conductivity or coefficient of permeability.

Petroleum: 40CFR280.12 defines the term *petroleum* to include crude oil or any fraction thereof that is liquid at standard conditions of temperature and pressure (60 degrees Fahrenheit and 14.7 pounds per square inch absolute).

Petroleum hydrocarbons (PHCs): hydrocarbons (i.e., compounds comprised of combinations of hydrogen and carbon atoms) that are components of petroleum (crude oil), including the various products that result from distillation of crude oil

Petroleum vapor intrusion (PVI): intrusion of petroleum hydrocarbon vapors into buildings or other structures

Porosity: the volume fraction of a rock or unconsolidated sediment not occupied by solid material but usually occupied by water or air (gas)

Preferential transport pathways: pathways through which contaminants may be transported at a higher rate than through surrounding materials. Preferential transport pathways are heterogeneities within geologic media and include features that are natural (such as facies changes, sand or gravel stringers, solution channels in karst, bedding planes and weathered surfaces, fractures, and joints) as well as man-made (such as utility corridors, trenches, other types of excavations).

Regulated substance: (a) Any substance defined in section 101(14) of the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) of 1980 (but not including any substance regulated as a hazardous waste under subtitle C), and (b) Petroleum, including crude oil or any fraction thereof that is liquid at standard conditions of temperature and pressure (60 degrees Fahrenheit and 14.7 pounds per square inch absolute). The term regulated substance includes but is not limited to petroleum and petroleum-based substances comprised of a complex blend of hydrocarbons derived from crude oil through processes of separation, conversion, upgrading, and finishing, such as motor fuels, jet fuels, distillate fuel oils, residual fuel oils, lubricants, petroleum solvents, and used oils.

RfC (reference concentration, inhalation): an estimate (with uncertainty spanning perhaps an order of magnitude) of a continuous inhalation exposure of a chemical to the human population through inhalation (including sensitive subpopulations), that is likely to be without risk of deleterious noncancer effects during a lifetime

Selective ion monitoring (SIM): a mass spectrometry scanning mode in which only a limited mass-to-charge ratio range is transmitted or detected by the instrument, as opposed to the full spectrum range

Semi-volatile organic compound (SVOC): an organic compound which has a boiling point higher than water and which may vaporize when exposed to temperatures above room temperature. Semi-volatile organic compounds include phenols and polynuclear aromatic hydrocarbons (PAHs).

Site assessment: see site characterization

Site characterization: (verb) the process by which site-specific information and data are gathered from a variety of sources to characterize the physical, biological, and chemical systems at a contaminated site. A primary objective of site characterization is delineation of the areal (both horizontal—longitudinal and lateral—transverse) and vertical extent of contamination. This includes changes in plume boundaries, changes in geochemical parameters that affect biodegradation, and contaminant mass (or concentration) increases or decreases. (noun) The product (e.g., CSM, report) resulting from the site characterization process. (Note: Site assessment, site investigation, site evaluation, and site check are all synonyms of site characterization.)

Site check: see site characterization

Site evaluation: see site characterization

Site investigation: see site characterization

Soil moisture: the water contained in the pore spaces in the unsaturated zone

Solubility: the amount of mass of a compound that will dissolve in a unit volume of solution

Sorption: a general term used to encompass the processes of absorption, adsorption, ion exchange, and chemisorption

Source material: material that includes or contains contaminants that act as a reservoir (either stationary or mobile) for migration of contamination to the ground water, to surface water, to air, (or other environmental media), or acts as a source for direct exposure. Contaminated ground water generally is not considered to be a source material although non-aqueous phase liquids (NAPLS [occurring either as residual- or free-phase]) may be viewed as source materials.

Source zone: the impacted area immediately surrounding the source of a release of regulated substances comprising source materials

Total petroleum hydrocarbons (TPH): a measure of the concentration or mass of petroleum hydrocarbon constituents present in a given amount of air, soil, or water. (Note: The term total is a misnomer, in that few, if any, of the procedures for quantifying hydrocarbons are capable of measuring all fractions of petroleum hydrocarbons present in the sample. Volatile hydrocarbons are usually lost in the process and not quantified. Additionally, some non-petroleum hydrocarbons may be included in the analysis.)

Travel time: the time it takes a contaminant to travel from the source to a particular point downgradient

Tribe: Indian tribe or tribe means an Indian or Alaska Native tribe, band, nation, pueblo, village, or community that the Secretary of the Interior acknowledges to exist as an Indian tribe pursuant to the federally Recognized Indian Tribe List Act of 1944, 25 U.S.C. 479a.

Underground storage tank (UST): 40CFR280.12 defines an *underground storage tank* as any one or combination of tanks (including underground pipes connected thereto) that is used to contain an accumulation of regulated substances, and the volume of which (including the volume of underground pipes connected thereto) is 10 percent or more beneath the surface of the ground. This term does not include any: (a) Farm or residential tank of 1,100 gallons or less capacity used for storing motor fuel for noncommercial purposes; (b) Tank used for storing heating oil for consumptive use on the premises where stored; (c) Septic tank; (d) Pipeline facility (including gathering lines) regulated under: (1) The Natural Gas Pipeline Safety Act of 1968 (49 U.S.C. App. 1671, *et seq.*), or (2) The Hazardous Liquid Pipeline Safety Act of 1979 (49 U.S.C. App. 2001, *et seq.*), or (3) Which is an intrastate pipeline facility regulated under state laws comparable to the provisions of the law referred to in paragraph (d)(1) or (d)(2) of this definition; (e) Surface impoundment, pit, pond, or lagoon; (f) Storm-water or wastewater collection system; (g) Flow-through process tank; (h) Liquid trap or associated gathering lines directly related to oil or gas production and gathering operations; or (i) Storage tank situated in an underground area (such as a basement, cellar, mine working, drift, pit, or tunnel) if the storage tank is situated upon or above the surface of the floor. The term underground storage tank or UST does not include any pipes connected to any tank which is described in paragraphs (a) through (i) of this definition.

Unsaturated zone: the zone between land surface and the capillary fringe within which the moisture content is less than saturation and pressure is less than atmospheric. Soil pore spaces also typically contain air or other gases. The capillary fringe is not included in the unsaturated zone.

Vadose zone: the zone between land surface and the water table within which the moisture content is less than saturation (except in the capillary fringe) and pressure is less than atmospheric. Soil pore spaces also typically contain air or other gases. The capillary fringe is included in the vadose zone.

Vapor intrusion attenuation factor (α): a parameter defined by Johnson and Ettinger (1991) to relate the vapor concentration of a volatile chemical inside the building to its vapor concentration at the subsurface source. This parameter, designated alpha (α), is defined mathematically as the vapor concentration in indoor air divided by the vapor concentration in soil gas at the source (with concentration being in the same units), and thus it is a ratio. The source is defined as the region of highest vapor concentration. Therefore, α values are always less than one. The vapor intrusion attenuation factor is an inverse measurement of the attenuation: α values *decrease* with *increasing* attenuation and α values *increase* with *decreasing* attenuation. In other words, α values represent the fraction of soil gas contaminant that reaches indoor air. Large α values (i.e., values approaching 1) indicate that a large fraction of the soil gas contaminant has reached the indoor air; therefore, little attenuation is taking place, whereas small α values indicate that a small fraction of the soil gas contaminant has reached the indoor air; therefore, significant attenuation is taking place.

Vapor pressure: the force per unit area exerted by a vapor in an equilibrium state with its pure solid, liquid, or solution at a given temperature. Vapor pressure is a measure of a substance's propensity to evaporate. Vapor pressure increases exponentially with an increase in temperature.

Vertical separation distance: the thickness of clean, biologically active soil that separates the source of contamination from a building basement, foundation, or slab

Volatile: is a tendency of a substance to vaporize or the speed at which it vaporizes. Volatility is indicated by a substance's vapor pressure. Substances with a higher vapor pressure will vaporize more readily at a given temperature than substances with a lower vapor pressure. A volatile organic compound is an organic compound which has a boiling point below that of water and which can easily vaporize or volatilize.

Volatile organic compound (VOC): organic compound that at room temperature and normal atmospheric pressure produces vapors that escape easily from volatile liquid chemicals. Volatile organic compounds include a variety of chemicals such as gasoline, benzene, toluene, xylene, formaldehyde, tetrachloroethylene, and perchloroethylene.

Volatilization: the process of transfer of a chemical from the aqueous or liquid phase to the gas phase. Solubility, molecular weight, and vapor pressure of the liquid and the nature of the gas-liquid interface affect the rate of volatilization.

Water table: the water surface in an unconfined aquifer at which the fluid pressure in the pore spaces is at atmospheric pressure

Weathering: the process during which a complex compound is reduced to its simpler component parts, transported via physical processes, or biodegraded over time

Wilting point: the minimal point of soil moisture the plant requires not to wilt. Wilting point values under field conditions are not constant for any given soil, but are determined by the integrated effects of plant, soil and atmospheric conditions.

1 Background

Exposure point concentrations (EPC) are the **average** chemical concentrations to which receptors are exposed over a specified duration within a specified geographical area. The geographical area about which a receptor moves and contacts contaminated media during the specified exposure duration is termed an exposure unit (EU). EPCs are also often referred to as representative concentrations.

This appendix describes the concept and methodology that should be used to estimate EPCs. This guidance provides general recommendations on procedures to accurately determine EPCs. These recommendations may not apply to all sites, particularly large, complex sites. Site-specific circumstances may require consultation with the Idaho Department of Environmental Quality (DEQ), the application of professional judgment, and reference to the more detailed literature cited herein. Other useful references are also included at the conclusion of this appendix.

In the site-specific application of the risk evaluation process, EPCs are used as input parameters in estimating the risk to a specified receptor for each complete route of exposure identified in the site conceptual exposure model (SCM) and each petroleum chemical of interest (COI). Risk management decisions are then made based on a comparison of the estimated risk with the regulatory specified target risk. This comparison is termed a forward-mode calculation. EPCs can also be used in what are termed backward-mode calculations when they are compared with calculated target levels for each complete route of exposure and each petroleum COI. In either mode, the calculation of EPCs is critical in the outcome of the risk evaluation.

Complications in the calculation of the EPCs may arise because the concept of EPC is often mistakenly associated with a site as opposed to an exposure pathway or the source. Since there may be several complete pathways at a site, several EPCs, one for each complete pathway, should be estimated. For example, estimation of the soil EPC for the pathway involving soil leaching and protection of ground water ingestion typically considers data over the entire soil profile from the source area. At the same site, soil EPC estimates for the direct contact route of exposure involving surficial soil would typically consider only the upper several feet of the soil profile and would focus on the portions of the site where receptors may travel. The accurate estimation of EPCs is complicated by several factors, including the following:

- Spatial variability in the concentrations
- Temporal variability in the concentrations
- Lack of sufficient, appropriately located, site-specific concentration data
- Poor definition or uncertainty in the location, size, or other characteristics of the EU

The uncertainty in the EPC introduced by some of these factors can be reduced by considering them during the development of the SCM and the sampling and analysis plan.

After samples have been collected and analyzed, the results need to be appropriately evaluated to produce sound estimates of EPCs. This evaluation includes assessing the following:

- Data quantity
- Data quality (which data are acceptable for use)
- Statistical methods (which methods to use)
- Which usable data apply to a specific EU

This guidance focuses primarily on the latter two issues.

2 Statistical Considerations for Estimating Exposure Point Concentrations

Numerous statistical methods can be employed to develop estimates of the exposure point (average) chemical concentration to which a receptor will be exposed. These methods include examining the maximum detected concentration, upper confidence limit (UCL) of the mean (for example the 95% UCL), arithmetic average, geometric average, area-weighted average, depth-weighted average, and volume-weighted average concentration (very rarely used). Associated with each of these methods are certain advantages, disadvantages, and constraints on their appropriate use. There is no uniformly accepted statistical methodology to estimate the EPC. Implicit in the decision to use any particular method is the need to acknowledge and account for the representativeness of the samples collected, the homogeneity of the defined EU, the statistical distribution of the data, the minimum data requirements of the statistical method used, and the uncertainty in the resultant data used to derive the estimated concentration.

From a practical perspective, several factors common to petroleum release sites may make the use of statistical methods to develop EPCs at a given site unrealistic, particularly for ground water. These factors include the following:

- Small release areas
- Dominantly subsurface releases, often at great depth
- Focus on source areas and not exposure pathways
- Limited sample numbers due to temporal/spatial constraints

2.1 Maximum Detected Concentration

The use of the maximum detected chemical concentration is required for comparison to screening levels during the screening level evaluation (see Section 3, Screening Level Evaluation, in the main body of the document). Depending on the quality of the site characterization data available, the maximum detected concentration can be used as EPCs in site-specific risk evaluations and will typically represent a conservative estimate of the average concentrations, particularly when sample numbers are low (i.e., four or less).

The effort necessary to calculate EPCs for certain complete pathways can be avoided by using the maximum media-specific concentrations when they do not exceed the target

levels or when the cumulative risk, calculated using maximum concentrations, does not exceed the target risk.

2.2 Upper Confidence Limit

The true population mean is a unique value that can be calculated only if the entire population has been sampled (i.e., the entire contaminated media analyzed). Since the entire population is almost never sampled, the true mean is never known. Thus, at best, only an estimate of the true population mean concentration is possible.

To account for the uncertainty associated with the estimated mean concentration, a confidence interval about the true but unknown mean is often constructed. The interval estimate includes a range and an associated degree of confidence that the true unknown mean lies within this range. In risk assessment applications, instead of calculating a two-sided confidence interval, a one-sided confidence interval is most often estimated.

For the calculation of EPCs, the U.S. Environmental Protection Agency (EPA) has recommended, in most cases, using the 95% upper confidence limit (UCL) of the mean (EPA 1992a). The upper limit for a one-sided 95% confidence interval of the mean is defined as a value that, when calculated repeatedly for randomly drawn subsets of site data, equals or exceeds the true mean 95% of the time. Alternatively, the true mean exceeds the UCL only 5% of the time. Ideally, a minimum of 8 to 10 samples is desirable to generate a 95% UCL. Although the UCL can be determined with fewer samples, doing so tends to results in the 95% UCL estimate being larger (large variances) than the arithmetic average and will sometimes exceed the maximum measured concentration. In these instances, the maximum measured concentration can be substituted for the 95% UCL or the user can decide to collect more samples to reduce the sampling variance.

Several issues commonly arise with environmental data sets that complicate the development of the confidence limit and should be evaluated through the use of an exploratory analysis prior to performing the calculation. These issues include the following:

- Determination of the distribution of the data chosen to represent the EU (normal, lognormal, or nonparametric [i.e., not conforming to a specific distribution]). This determination includes decisions as to what analysis and statistical tests to perform, how to interpret the test results, and how to treat the data once a determination is made.
- How to handle censored data and/or skewed data (typically due to non-detect [ND] values).

Depending on the nature of the underlying distribution of the data (or lack thereof), the one-sided 95% UCL can be calculated using a number of methodologies. The details regarding these methodologies are beyond the scope of this guidance.

EPA has developed technical guidance, a user's guide, and computer software (ProUCL 4.1) for calculating the UCL based on parametric (normal and lognormal distributions) and nonparametric distributions and when data sets have ND observations

(EPA 2011a, 2011b). The ProUCL technical guidance (Sections 1.7.1 and 1.7.2) describes the minimum data set conditions under which the ProUCL software will perform UCL calculations. These guidelines generally involve data set sizes greater than or equal to five with more than one detected value.

For samples collected using a multi-increment sampling approach, data set sizes as small as three may be sufficient to calculate a UCL. The Interstate Technology Regulatory Council (ITRC) has developed a guide for incremental sampling methodology (ITRC 2012).

For simpler data sets (with few or no ND values), DEQ has developed the IdahoUCL software, which is available at http://www.deq.idaho.gov/risk-evaluation-manual.

2.3 Arithmetic Average

Using the arithmetic average (or mean) is similar to the UCL with the disadvantage that no estimate of the uncertainty, variability of the average, or information regarding the underlying distribution of the population is incorporated into the value generated. For a population that is normally distributed, the estimates generated using the 95% UCL versus the mean tend to converge as the number of samples approaches 20 to 30 (EPA 1992a).

2.4 Geometric Average

The geometric average is sometimes used as an estimate of the mean of lognormally distributed variables. It represents the value in the original scale of the mean of the transformed variable. It is, however, a biased estimate of the mean, and statistical texts such as *Statistical Methods for Environmental Pollution Monitoring* (Gilbert 1987) caution against its use in environmental applications. *Statistical Methods for Environmental Pollution Monitoring* (Gilbert 1987) or *ProUCL 4.1 Technical Guide* (EPA 2011a) should be consulted when attempting to develop an unbiased estimate of the mean of a lognormally distributed variable. Exploratory data analysis should be conducted to confirm an assumption that the variable is lognormally distributed prior to calculating an EPC. As with the arithmetic average, no estimate of the uncertainty or variability is incorporated into the value generated by the geometric average and it may not be conservative.

2.5 Area-Weighted Average

Where sampling locations are unevenly spaced, area-weighted averaging methods can be employed to generate an estimate of the average concentration across an area. This calculation is done by generating an area (or Thiessen polygon) associated with each sampling location, assigning a "weight" to each data point based on the area of the polygon associated with that point, and summing the weighted data point values. One advantage of the method is that it is useful in characterizing areas where the number of sample points is low.

The method also has several disadvantages. First, the shape, and consequently the contribution of an area associated with a sample location to the "average," is totally dependent on the spatial distribution of all data points and may not be reflective of the true distribution of contaminants at a site. Second, since each polygon is associated with one sample point, no estimate of the accuracy or error in the average value is possible. Finally, the method, unlike several other interpolation schemes, does not assume that points that are closer together are more similar than points that are farther apart. The method for calculating an area-weighted average using Thiessen polygons is discussed in section 5.

2.6 Depth-Weighted Average

Depth-weighted averaging methods are used to develop an average or EPC for a specific borehole where multiple samples at varying depth intervals have been obtained. In characterizing a source area with multiple boreholes, the depth-weighted averages from each borehole can be used in a 95% UCL calculation. The methodology for depth-weighted averaging is described in EPA's *Soil Screening Guidance: User's Guide* (EPA 1996, section 2.3).

2.7 Volume-Weighted Average

Volume-weighted averaging methods are a combination of area- and depth-weighted averaging techniques. They are rarely used in risk assessment evaluations.

3 General Considerations for Estimating Exposure Point Concentrations

Estimating EPCs requires considering several issues. Prior to performing the computations, consider the information in the following sections.

3.1 Surface and Subsurface Soil Concentrations

When evaluating exposure point soil concentrations consider the following:

- The spatial resolution of the data must be sufficient. While the exact number of necessary samples cannot be specified, data should be available from areas of known or likely sources, and the EU should be defined for a given pathway and receptor.
- Historical data should be examined closely prior to inclusion in the EPC estimate, particularly if the petroleum COIs are susceptible to biodegradation (such as petroleum hydrocarbons), volatilization, or leaching. If sufficient new data are collected, they may be used for risk evaluation and the old data may be disregarded. A new release requires the collection of additional data.
- If there is a "high" density of soil samples (>30) for a homogeneous EU and sample locations are approximately equally spaced, the arithmetic average may be

used instead of the 95% UCL or the area-weighted average. This method is acceptable because the area-weighted average, arithmetic average, and UCL concentrations will tend to converge (EPA 1992a) if the underlying population can be assumed to be normally distributed. The >30 value mentioned above should also be considered in relation to the size of the EU and may not be appropriate for very large EUs.

- ND soil samples located at the periphery of the EU (e.g., the footprint of a building) should not be used.
- ND samples (also referred to as left-censored data) located within the EU require special treatment. The EPA has recently discouraged using replacement methods (such as half the detection limit) (EPA 2011a). The proportion of ND samples in the subject data set and whether multiple detection limits exist will affect the specific methods used to generate summary statistics and the UCL. EPA ProUCL 4.1 software has several options for handling left-censored data. Consult the technical guidance accompanying the software to determine which method is most appropriate for the specific data set and how to treat the censored data (EPA 2011a).
- If multiple surficial soil samples and/or multiple subsurface soil samples are available from the same borehole within the EU, the depth-weighted average or arithmetic average concentration of these samples may be used. If the samples are equally spaced, the depth-weighted average concentration will be the same as the arithmetic average concentration.
- An alternative to using discrete soil samples to calculate the UCL is to use incremental sampling methodologies (USACE 2009; Hawaii DOH, section 4 2008; Alaska DEC 2009; ITRC 2012). Incremental sampling is a sampling approach to obtain a pooled sample for analysis that has an analyte concentration representative of the EU. While it is similar to composite sampling, the incremental approach takes into account sample size to reduce variability and also allows for the calculation of a UCL while only requiring a few samples for laboratory analysis. It typically requires greater up-front planning with respect to sampling design, methodology, and defining of data quality objectives than traditional composite sampling.
- If vapor intrusion is a potentially complete pathway, collecting soil vapor data, in lieu of soil samples, for characterizing the potential risk should be considered. Consult Appendix G (Evaluation of the Vapor Intrusion Pathway) and section 4.5 of this appendix for sampling details.

3.2 Ground Water Concentrations

Follow the guidelines listed below to account for the temporal and spatial variation in ground water concentrations. These recommendations apply primarily to evaluation of ground water data for the purpose of estimating EPCs for risk evaluation.

They are not intended for cases where other monitoring objectives, such as determining compliance with cleanup criteria or site closure, are the primary goals.

- For wells with a clear increasing or a decreasing trend, data from the most recent 12 months or the 4 most recent measurements should be averaged (use whichever covers the longer duration). Note that for wells with increasing trends, continued monitoring may be needed until the trend stabilizes or decreases. The need for additional monitoring is a site-specific determination that is dependent on a number of factors, including the magnitude of measured concentrations in relation to risk-based criteria, the degree to which samples are representative and address site factors such as seasonality, and the estimated travel time of contamination from the release area to ground water and to potential receptors. For example, four measurements, taken at appropriate intervals over the course of a year, show an increasing trend but are all below applicable risk criteria. Further monitoring to develop an EPC may not be necessary.
- For wells with stable or fluctuating concentrations with no apparent trend, data from either the most recent 24 months or the 8 most recent measurements should be used to develop a 95% UCL.
- If site ground water analytical data are limited (number of wells or number of sampling events) and prevent adequate statistical analysis, using the maximum concentrations is preferred. Using the average concentration is discouraged, particularly if the plume stability status (increasing, decreasing, or stable) with respect to the release is unknown or the representativeness of the available data is in question.
- While developing the EPC for wells described by the first two bullets above, the treatment of left-censored data (concentrations below detection limits) deserves special consideration and may require specialized analysis techniques. Replacement techniques (such as using half the detection limit) are currently discouraged by the EPA (EPA 2011a). If the percentage of ND values is a significant percentage of the total number of data points (>25%), the representativeness of the data set for the EU in question should be evaluated.
- Wells with concentrations consistently below detection limits in the periphery of the EU should not be used.
- For wells that contain free product where it is not possible to obtain a representative dissolved phase sample, the use of the effective solubility of petroleum COIs should be considered as a conservative surrogate for their chemical concentration in estimating EPCs.

Two useful documents that provide guidance on the statistical evaluation of ground water monitoring data are the EPA's unified guidance (EPA 2009) and DEQ's *Statistical Guidance for Determining Background Ground Water Quality and Degradation* (DEQ 2009).

4 Calculation of Exposure Point Concentrations

An EPC is necessary for each complete exposure pathway at a site. Based on the pathways typically considered in the risk evaluation process, the EPCs listed below are typically needed for each media.

4.1 Surficial Soil (0–1 Foot below Ground Surface)

The risk evaluation process requires consideration of two pathways of exposure associated with the surficial soil: 1) the ingestion of chemicals in ground water due to leaching of residual chemicals present in the surficial soil and 2) the accidental ingestion of soil, outdoor inhalation of vapors and particulates from surficial soil emissions, and dermal contact with surficial soil. These two pathways are referred to as the ground water protection and direct soil contact pathways, respectively. Thus, at most, two different surficial soil EPCs are required, though typically one EPC estimate can be used for both pathways.

4.1.1 Exposure Point Surficial Soil Concentration for the Ground Water Protection Pathway

Figure 1 shows a schematic of the soil leaching to ground water pathway. The evaluation of this pathway for surficial soil assumes that the contamination does not extend greater than 1 foot below ground surface. If this is not the case, then samples taken in the surficial soil zone should be included with those from greater depth and evaluated together.

The conceptual model for this pathway also assumes that the leachate from the surficial (or subsurface) soil source travels vertically downwards to the water table without any lateral or transverse spreading. Thus, the horizontal dimensions of the surficial (or subsurface) soil source and the ground water source are identical. Estimating the source dimensions requires considerable professional judgment. Factors typically considered in making these estimates include historical knowledge of where a spill or source was located, visual clues such as soil discoloration, and laboratory data (taking care not to include samples with ND results.

Irrespective of the manner in which the source area is identified, it is important to indicate the dimensions of the source on a map. The exposure point surficial soil source concentration should be estimated using only the surficial soil data collected within the delineated source zone. The method used to derive the EPC should typically be either the UCL of the mean (when the quantity and characteristics of the data available allow a statistical analysis) or the values derived from an incremental sampling approach.

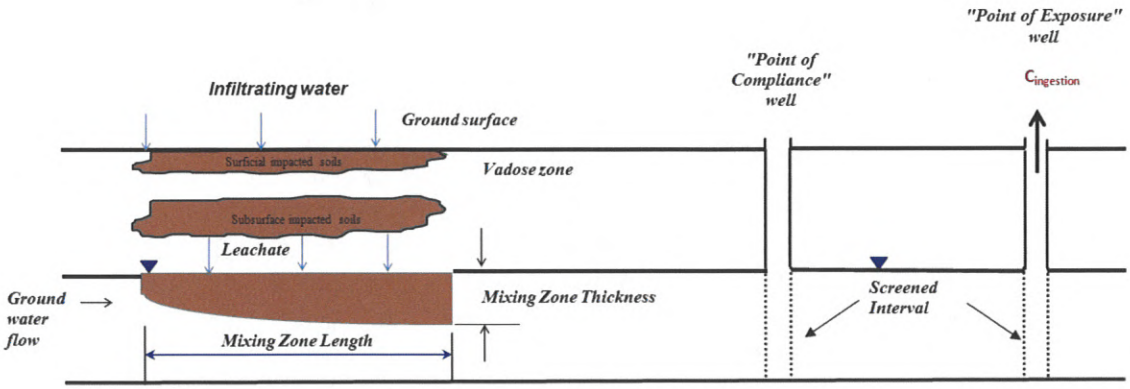

Figure 1. Schematic of soil leaching to ground water

4.1.2 Exposure Point Surficial Soil Concentrations for the Direct Contact Pathway

For this pathway, the exposure point surficial soil concentration has to be based on the receptor's EU (i.e., the area over which the receptor may be exposed to the surficial soil). The exact location of this area is often difficult to estimate since it must be representative of a period of time equal to the receptor's exposure duration (for example, up to 30 years for residential land use and about 7 years for nonresidential land use). In most cases, it is reasonable to assume that the receptor will access all portions of the EU in a random manner. Under current conditions, in the absence of specific information about the receptor's activities, the unpaved portion of the site may be considered as the receptor's approximate EU. Where volatile organic compounds (VOCs) are included in the list of potential petroleum COIs and/or the paved portion is in poor condition or consists of a material that does not limit VOC migration, this guide would not apply. For potential future exposures, if current condition cannot be assumed to continue, the assumption should be made that the pavement is removed, exposure to surficial soil is possible, and the entire site should be considered as the EU.

If the possibility exists that, for a future use residential scenario, contaminated subsurface soil existing under a current nonresidential scenario may be brought to the surface and result in direct contact residential exposures at the surface, the appropriate subsurface data should be included in the estimate of the EPC.

To estimate the EPC for this pathway, it would be necessary to estimate the receptor's area of exposure and determine the number of soil samples available within this EU. This information should be used to estimate the 95% UCL or an area-weighted average concentration using the procedures discussed in section 5. The use of an incremental sampling approach for characterizing EPCs for this route of exposure may be particularly well-suited and efficient.

4.2 Subsurface Soil (Greater Than 1 Foot below Ground Surface)

The risk evaluation process includes two pathways of exposure associated with subsurface soil: 1) the ingestion of chemicals in ground water or exposure to surface water impacted by discharge of contaminated ground water resulting from leaching of chemicals in subsurface soil and 2) indoor inhalation of vapor emissions. These two pathways are referred to as the ground water protection and vapor intrusion pathways, respectively. Thus, two different subsurface soil EPCs are required (one for each complete pathway). Additional EPCs may be required if the receptor's EU for current and future conditions is different.

4.2.1 Exposure Point Subsurface Soil Concentration for Ground Water Protection Pathway

The leachate from the subsurface soil source is assumed to travel vertically downwards without any lateral or horizontal spreading (Figure 1). Thus, the EPC for this pathway should be based on the subsurface soil concentrations measured within the source area.

As in the case of the surficial soil concentration protective of ground water (section 4.1.1), the exposure point subsurface soil source concentration would be the average concentration calculated using the data within the soil source area. If the source area is small (several tens of feet across), typically smaller numbers of soil samples are available. In this case, the 95% UCL should first be calculated if the sample numbers for applicable data are adequate. If the 95% UCL exceeds the maximum concentration, it may be appropriate to use the maximum concentration.

4.2.2 Exposure Point Subsurface Soil Concentration for Vapor Intrusion Pathway

The use of soil concentration data and development of exposure point soil concentrations for evaluation of vapor intrusion, while allowable, is not as desirable as the use of soil vapor data. The use of soil vapor data is discussed in more detail in Appendix G (Evaluation of the Vapor Intrusion Pathway) and in section 4.5 of this appendix.

The default methodology and model used to estimate the risks resulting from the indoor inhalation of vapors emanating from a contaminated subsurface soil source is the Johnson and Ettinger model (Johnson and Ettinger 1991). The Johnson and Ettinger model assumes that the chemicals volatilize from a subsurface soil source, travel vertically upwards via diffusion without any lateral or transverse spreading, and enter the building via advection through cracks in the foundation. Because this model does not account for biodegradation (an important attenuation process for petroleum hydrocarbon chemicals), the predictions are generally considered conservative for these chemicals. Other models that do incorporate biodegradation, such as the BioVapor model (API 2010) may also have applicability.

To be completely consistent with the Johnson and Ettinger conceptual model, the EPC for this pathway would be based on the soil concentrations measured in the soil directly below the enclosed space. In many cases, this is not possible. Furthermore, depending on site conditions (such as the location of pavement, preferential pathways, and site lithology), vapors from source areas adjacent to but not under an existing structure may contribute to indoor inhalation exposures. The goal should be to characterize the average soil concentration in the source area that may potentially contribute vapors to any existing or potential future structures. If the pathway is considered complete for current conditions, appropriate samples for EPC estimates should be selected to achieve this goal. Samples should be focused in the immediate vicinity of any existing structures as well as within 50 feet of the structure. If free product is suspected or known to exist in the area around the structure, sampling locations should be extended to 100 feet. If current and reasonably anticipated future land uses are the same, the EPC calculation is unchanged for future uses.

To evaluate EPCs for potential future vapor intrusion (e.g., in the event that an enclosed structure is constructed on top of contaminated soil), it is necessary to determine the nature of any future structure and estimate the size (footprint) of the structure and its location.

If the location and characteristics of future structures are known, the EPC should be conservatively estimated using samples from that vicinity, including the buffers mentioned above for existing structures. If the nature of future structures is not known, the assumption should be made that a structure could be placed anywhere on the property in question and potentially located directly over the source. The size of the structure would be assumed to be similar to that of the likely future land use, in most cases either residential or nonresidential. The default size of a residential structure assumed in this guidance is approximately 40 feet by 40 feet. For sites where the footprint of the current and likely future enclosed spaces are different, different exposure point subsurface soil concentrations (one for current conditions and one for future conditions) may be necessary. The 95% UCL or area-weighted average methods may be used, as appropriate. Where multiple boreholes with several depth interval samples are available, a depth-weighted average from individual boreholes can be developed.

4.3 Exposure Point Concentration for Protection of a Construction Worker

The risk evaluation process includes the evaluation of one pathway of exposure for construction workers: accidental ingestion, dermal contact, and outdoor inhalation of vapors and particulates from soil.

For the construction worker, no distinction is made between the surficial and subsurface soil because subsurface soils may be exposed during construction. To estimate the EPC for the construction worker, it is necessary to identify the depth, areal extent, and number of samples taken within the zone of construction. The potential future depth of construction can be estimated by contacting local construction firms and identifying the typical depth of utilities on and adjacent to the site, contacting local utility companies, or

using as-built plans for proposed facilities if they exist. If the areal extent of the construction area is not known, it may be conservatively estimated as the source area. If sample results are available for several depth intervals, these should be averaged using depth weighting. The depth-weighted averaged values from multiple boreholes could then be combined to calculate a 95% UCL or area-weighted average, as appropriate. The EPC would be the depth-weighted average concentration within this zone of construction.

4.4 Ground Water

The risk evaluation process requires evaluating two routes of exposure associated with shallow ground water: 1) ingestion of ground water and 2) indoor inhalation of vapor emissions from ground water. Where multiple aquifers are present, the shallowest aquifer is typically the aquifer first considered for both pathways. Site-specific circumstances—such as the disappearance of the shallow aquifer or transport of contamination to the deeper aquifer—may require evaluation of both aquifers. Characterization of petroleum COIs in both aquifers should still be performed. At a minimum, two different ground water EPCs, one for each complete pathway, are required.

4.4.1 Exposure Point Compliance Well Concentration for Ground Water Protection Pathway

For the ingestion of ground water pathway, maximum contaminant levels (MCLs) or equivalent concentrations have to be met at the point of exposure location. Often, the point of exposure well location is hypothetical and data may not be available. Alternatively, if a point of exposure well is present, an upgradient sentry or compliance well is often used as an early warning monitoring location. In both of these cases, ground water transport models are used to calculate the predicted concentrations at the point of exposure based on source area concentrations, the allowable concentrations in the source area, or an alternate point of compliance location concentration that will result in acceptable concentration at the point of exposure. In any case, EPCs will need to be estimated for the source area or for the alternate point of compliance location. In addition, one or more compliance wells have to be identified, and target compliance well concentrations (typically higher than the exposure well concentration) have to be calculated at these wells.

To evaluate this pathway, the EPCs in the source area, point of compliance, or point of exposure locations should be calculated based on the measured concentrations as discussed below. In most cases, a rule of thumb is that measurements taken more frequently than quarterly would not be considered statistically independent samples, would not be accepted to meet the specified number of measurements, and should not be used for statistical analysis and hypothesis testing (DEQ 2009). Methods to evaluate temporal independence are discussed in EPA 2009 and DEQ 2009.

- For wells with no clear trend, the EPC should be estimated as the 95% UCL if the data permit. Where the calculated 95% UCL exceeds the maximum concentration or if the data are not suitable for statistical analysis, the maximum concentration should be used as the EPC. For compliance wells with stable, clearly decreasing,

or clearly increasing trends, the EPC is estimated as the 95% UCL of the most recent 1 year of data or most recent 4 measurements, whichever represents the longer time duration. For wells with an increasing concentration trend, continued monitoring may be needed until the trend stabilizes. Quarterly data for at least 1 year is recommended. The data should be pooled for source area characterization where multiple wells are available (DEQ 2009). Wells clearly not part of the source area of contamination should not be included in the calculations.

4.4.2 Exposure Point Ground Water Concentration for Protection of Indoor Inhalation Pathway

Ground water concentrations protective of indoor inhalation are commonly estimated using the Johnson and Ettinger model (Johnson and Ettinger 1991). This model assumes no lateral or transverse spreading or attenuation of the vapors as they migrate upward from the water table through the capillary fringe, the unsaturated zone, and into the enclosed space. Thus, the EPCs for this pathway should be based on the ground water concentration measured within and adjacent to the footprint of the building. Refer to section 4.2.2 for discussion related to the future land use footprints and their relationship to the impacted area.

For the indoor inhalation of vapor emissions from ground water, multiple EPCs may be required if the plume has migrated below several current or potential future buildings. For example, if a plume has migrated or is likely to migrate below two different buildings (for example on-site and off-site buildings), separate on-site and off-site EPCs should be estimated.

If the plume has migrated below several buildings with similar receptors (residential or commercial), it may be sufficient to evaluate this pathway only for the building below which the concentrations are the highest and/or the depth to ground water is the lowest. If this building is protective of indoor inhalation exposures, it may not be necessary to evaluate other buildings.

The plume may not be in the proximity of current structures. If assumed future land use includes the possibility of building structures in the vicinity of the plume, a similar calculation of EPCs and risk should be made using appropriate assumptions about the location and type of future structures.

While the target ground water concentrations are based on the assumption of no lateral or transverse spreading of the vapors as they diffuse upwards to the building, site characteristics such as site lithology and preferential pathways may result in lateral migration towards a structure. For this reason, the EPCs should be conservatively based on data gathered adjacent to the structure. After identifying the locations of the building footprints and the appropriate ground water monitoring data within and adjacent to each footprint, the 95% UCL or area-weighted average concentration within each footprint may be estimated, as discussed in section 5.

4.5. Soil Vapor

Soil vapor is used exclusively to evaluate the risk posed via the vapor intrusion pathway. Many of the same considerations discussed for the development of EPCs using soil data in section 4.2.2 also apply to soil vapor data. However, one important difference is that, similar to ground water concentrations, the number of soil vapor sample locations is typically fewer than with soil data and the use of statistical methods is precluded. In most cases, because of the variability commonly observed with vapor measurements and the uncertainty of vapor flow paths from the subsurface into indoor spaces, it is preferable to use the maximum concentrations measured within the defined EU. Where multidepth sampling of soil vapor has demonstrated attenuation of concentrations and the presence of a sufficient thickness of oxygenated soil conditions, the use of lower concentrations may be acceptable. Sufficient sample numbers are more often available where source areas or the buildings under consideration are large. In these situations, the use of area-weighted averaging or other statistical methods may be appropriate.

5 Estimating Area-Weighted Exposure Point Concentrations

Area-weighted EPCs can be estimated using the Thiessen polygon method (Fetters 1993; Linsley et al. 1975). If the available data are located on a uniform grid, the area-weighted average would be the same as the arithmetic average. If the dimensions of the source and the receptor's EU are relatively small (several tens of feet across) and very few (1 to 6) soil samples are available within the soil source, the arithmetic average concentration may be used as an approximation of the area-weighted average concentration.

5.1 Step 1: Identify the Exposure Unit

The first and most critical step is to identify the size and location of the EU over which the area-weighted EPC has to be estimated. The location and size of this EU will often vary depending on the pathway being evaluated. Specific guidance on the location of the receptor's area of exposure has been discussed in sections 3 and 4. Area-weighted concentrations can only be estimated if multiple samples have been collected within the unit. If several samples are available just outside the EU, it may be reasonable to extend the size of the unit to include this data. If the values of these samples are ND, they should not be included. This exclusion is technically justified since at most sites the location of the EU is approximate at best.

As part of Step 1, the various EUs for which area-weighted concentrations are desired should be drawn on a site map. The location of data points (soil borings, monitoring wells, etc.) should also be clearly labeled on the map.

If the borings or monitoring wells within the EU are located in a regular grid, the calculation of an area-weighted average is unnecessary and the user should proceed with an EPC calculation using a different method, such as the 95% UCL.

5.2 Step 2: Subdivide the Exposure Unit

The EU, identified in Step 1, is discretized into polygonal elements by connecting the sampling points within each EU (also identified in Step 1) and drawing perpendicular bisectors to these lines to form polygons. The area of each Thiessen polygon is then estimated.

5.3 Step 3: Estimate Exposure Point Concentrations for Each Thiessen Polygon

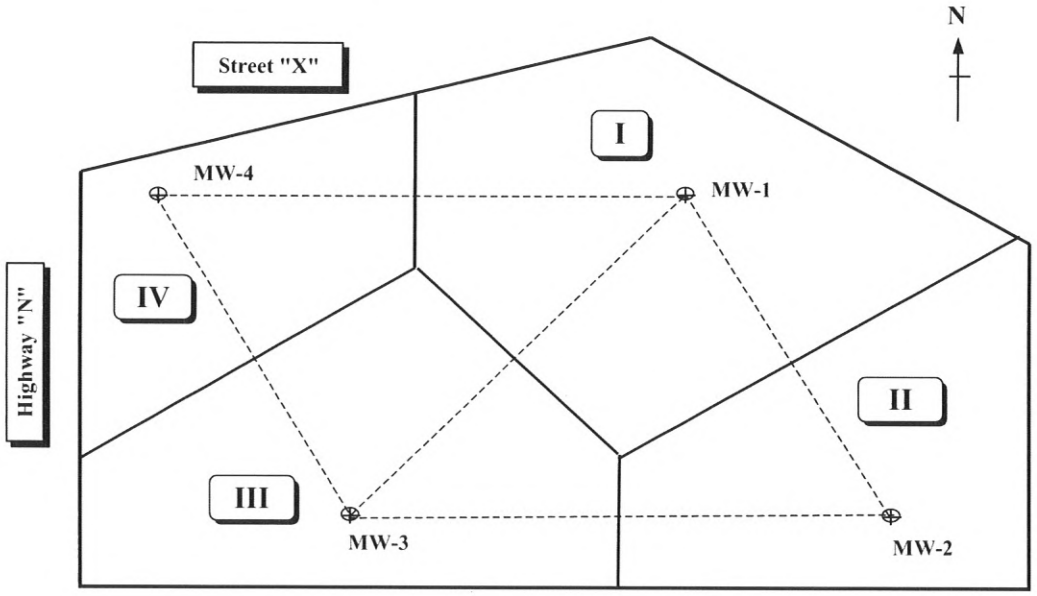
The concentration measured at the sampling location within each polygon is considered representative of the area of each polygon. As discussed in section 3, if multiple data are available from a location (either multiple depths or dates), compute the arithmetic average concentration of each petroleum COI measured at that location. The arithmetic concentration is then considered representative of the polygon.

5.4 Step 4: Estimate Area-Weighted Average Concentration for the Exposure Unit

The area-weighted average concentration for the EU is estimated using Equation 1:

$$C_{area} = \frac{\sum_{i=1}^{i=n} (A_i * C_{avg,i})}{A_{Total}} \qquad \text{(Equation 1)}$$

Where,



C_{area} = area-weighted average concentration over the EU [mg/kg]

A_i = area of each Thiessen polygon [m^2]

A_{Total} = total area of the polygons (i.e., area of the EU) [m^2]

$C_{avg,i}$ = mean of soil or ground water concentrations measured within the polygonal element *i* [mg/kg]

An example application of the Thiessen polygon method is schematically shown in Figure 2.

Polygonal Element	Mean Soil Concentration $C_{avg,i}$ mg/kg	Area of the Element A_i m^2	$A_i * C_{avg,i}$ m^2 - mg/kg	Area Weighted Average Concentration mg/kg
I	2	604	1208	
II	1.8	398	716.4	
III	1.2	578	693.6	
IV	1	234	234	
	TOTAL	**1814**	**2852**	
Area Weighted Average Concentration = $C_{area} = \frac{\sum_{i=1}^{i=n}(A_i * C_{avg,i})}{A_{Total}}$				**1.57**

Figure 2. Thiessen polygon method

6 Recommendations

- For most pathways, 95% UCL techniques are recommended for development of EPC estimates of average concentrations. For cases where the number of samples is low (four or fewer) and/or the number of ND values is high, the use of the maximum concentration may be most appropriate. The use of the maximum may also be appropriate when the calculated 95% UCL exceeds the maximum concentration measured at the site and the collected data are considered representative of site and EU conditions.
- The use of area-weighted average methods is not recommended for most pathways, but may be justified in developing EPCs for the surficial soil pathways. The inclusion of methods that evaluate and incorporate spatial uncertainty into the area-weighted average calculation increases the validity of the estimate derived (Burmaster and Thompson 1997).

Introduction

This appendix presents general guidance on the applicability and implementation of remediation by natural attenuation (RNA) at petroleum release sites in Idaho. Its primary focus is on attenuation of ground water contamination. Attenuation of petroleum hydrocarbons has also been documented in other media such as soil and soil vapor. Attenuation in soil vapor is addressed in Appendix G, which discusses evaluation of the vapor intrusion pathway. This appendix is divided into three parts:

- Part I presents a brief overview of the science of natural attenuation (NA)
- Part II presents the regulatory requirements for implementing NA as a remedial option
- Part III discusses the techniques available to support, quantify, and implement NA as a remedial option

This document should be used in conjunction with the *Idaho Risk Evaluation Manual for Petroleum Releases* (REM) and publicly available literature when implementing RNA. Additional information is available in the references provided at the end of this document.

PART I: The Science of Natural Attenuation

Part I presents an overview of the science of NA, including the following topics:

- A brief overview of the processes that constitute NA (section 2)
- A description of how biodegradation operates in attenuating petroleum hydrocarbons (section 3)
- A description of the indicators of NA of hydrocarbon plumes (section 3.5)

1 The Concept of Natural Attenuation

The term natural attenuation refers to the reduction in concentration or mass of chemicals in a media due to the effects of various environmental fate and transport processes. NA occurs without human intervention. Although NA is applicable to a reduction in concentration in any medium (e.g., air, surface water, ground water), in this appendix it refers to the reduction in concentration of a dissolved ground water contaminant plume. For a ground water plume, environmental fate and transport processes include physical processes (advection, dispersion, dilution, sorption, and volatilization); chemical processes (hydrolysis, oxidation, and reduction); and biodegradation processes (aerobic and anaerobic). Physical processes are nondestructive in that they redistribute the chemicals in the environment without affecting the total mass of the individual chemical. Chemical transformation processes and biodegradation result in the transformation of the parent chemical into other chemicals referred to as daughter products.

The only human action involved in RNA is monitoring to demonstrate that concentration reduction is occurring at a reasonable rate. Depending on site-specific conditions, RNA may be used as a stand-alone corrective action strategy or in combination with other engineered remediation alternatives.

This guidance focuses on using NA on sites contaminated with petroleum products. NA has also been used at sites with other classes of contaminants, such as metals, explosives, and pesticides (USACE 1999; SNL 1997). The same concepts for evaluation, requirements for site characterization, and demonstrations as to effectiveness are required regardless of the class of contaminant. A general approach to the evaluation of the bioremediation aspects of NA for a range of biotreatable compounds is described in ITRC 2002.

2 Overview of Natural Attenuation Processes

Although each contaminated site is unique, for this discussion it is useful to consider a generic site where a petroleum spill has occurred. The soil immediately below and around the point of release becomes contaminated, and the contaminant front moves downward. The downward movement of the contaminant front continues until one of the following three conditions occurs:

- The soil sorption capacity exceeds the amount of contaminant available.
- An impermeable barrier is encountered and the contaminant spreads horizontally.
- The contaminant reaches the water table and, if it is a light non-aqueous phase liquid (LNAPL), spreads horizontally.

The term LNAPL relates to the density of the released contaminant. LNAPLs are chemicals that are liquid at ambient temperature but lighter than water. For example, the density of toluene is 0.866 grams per cubic centimeter (g/cc) compared to a density of 1 g/cc for water.

After the contaminant movement has stopped, the soil through which it traveled is contaminated with residual chemicals that act as a contaminant source for the ground water plume. Figure 1 shows a schematic of a LNAPL moving through the soil to the ground water.

When rainwater infiltrates through the residual contaminated soils, it dissolves and leaches out the soluble components. For petroleum hydrocarbons, the toxic soluble chemicals include, but are not limited to, benzene, toluene, ethylbenzene, and xylene (BTEX); the soluble additives methyl tertiary butyl ether (MTBE) and ethylene dibromide; and smaller fractions of other less-soluble constituents. After undergoing NA processes in the unsaturated zone, these dissolved chemicals reach the water table, mix with ground water, and move with the ground water to form a dissolved plume. At sites where the spill is of a sufficient quantity to reach the water table and form an LNAPL layer on the water table, soluble constituents from the LNAPL gradually dissolve in ground water and form a dissolved ground water plume.

Additionally, vapors of volatile hydrocarbons (chemicals with a Henry's Law constant greater than 1×10^{-5} atm-m^3/mole) will spread outwards from the contaminated soil and dissolve in soil moisture and ground water.

As the dissolved plume moves through the unsaturated and the saturated zones, its concentration decreases due to the combined influence of several NA processes. Each of these processes is briefly discussed below.

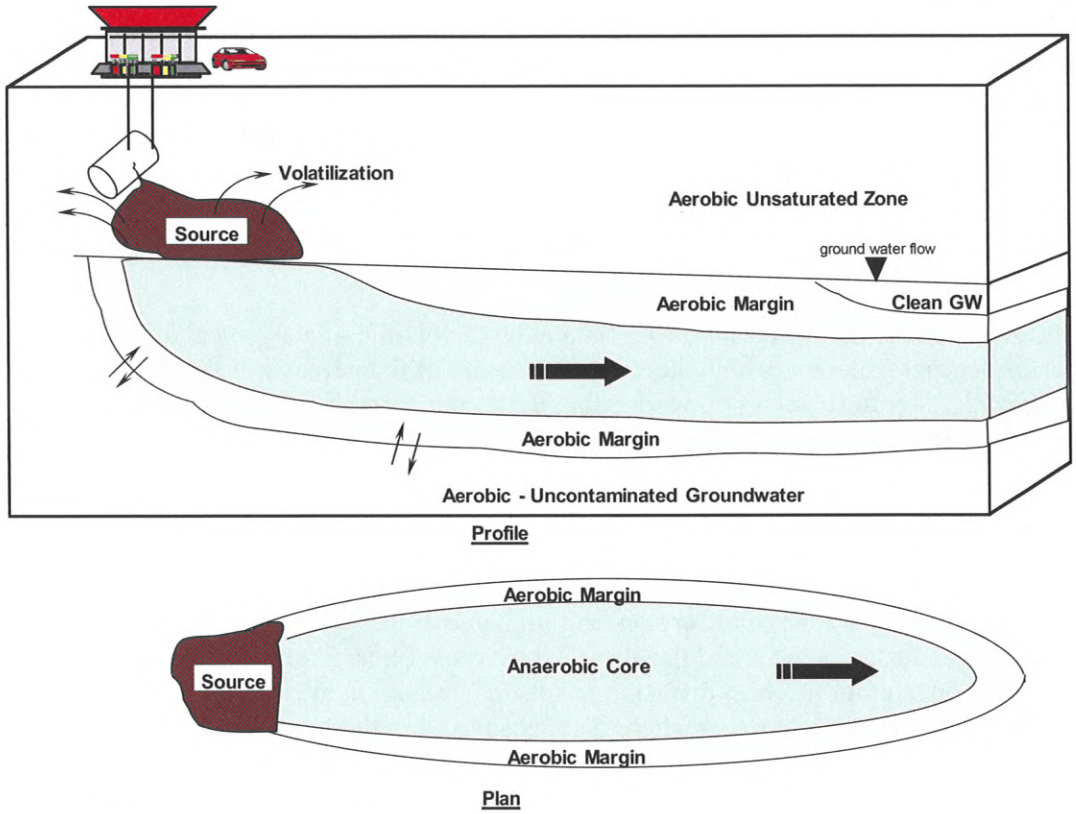

Figure 1. Schematic of a hydrocarbon release

2.1 Advection

Advection refers to the bulk movement or flow of water caused by differences in density, temperature, or pressure. In most aquifers, flow occurs predominantly due to hydraulic gradients, which may be natural—resulting in regional ground water movement—or man-made, caused by pumping or artificial recharge. In saturated zones, hydraulic gradients may exist in horizontal and vertical directions, resulting in complex three-dimensional flow patterns. However, at most sites there exists a predominant flow direction that results in the migration of most mass.

As water moves in the saturated zone, it carries with it the dissolved constituents. The process results in the migration of dissolved constituents in the saturated zone without a change in concentration and is termed advection.

Parameters required to estimate the volume of water moving through a saturated zone include the Darcy velocity and the cross-sectional flow area. Darcy velocity is estimated using hydraulic conductivity and hydraulic gradient.

Hydraulic conductivity may be estimated using a variety of methods, including slug tests, pump tests, grain size distribution, and literature values corresponding to the site stratigraphy. For most saturated zones, hydraulic conductivity varies in the horizontal and vertical directions.

Site-specific values of hydraulic gradients are estimated based on water-level measurements in monitoring wells, or piezometers. When estimating horizontal hydraulic gradients, it is important to compare data from wells screened in the same saturated zone. Wells screened in different zones or at different depths (e.g., cluster wells) can be used to estimate the vertical hydraulic gradient between the zones. Site-specific hydraulic gradients may exhibit seasonal and spatial variations (in magnitude and direction) due to a variety of factors such as pumping, seasonal flow in surface water bodies, and seasonal variations in rainfall.

Another related parameter used to estimate the travel time of a chemical due to advection is the seepage velocity, which requires an estimate of the porosity of the media. Typically, literature values corresponding to the aquifer type (e.g., sand or silt) are used to estimate porosity.

2.2 Molecular Diffusion

Molecular diffusion refers to the transport of chemical mass from a zone of higher concentration to a zone of lower concentration due to the movement of molecules. The effect of diffusion is to spread the chemical mass over a large area and hence reduce the overall concentration. Thus, diffusion results in a reduction in concentration by dilution. In most ground water systems where there is advection, the attenuation in concentration or the chemical mass transport due to diffusion is small and often negligible. However, in no-flow or low-flow situations, diffusion can be an important attenuation mechanism.

Molecular diffusion is quantified using Fick's Law, and the parameter required to quantify diffusion is the effective diffusion coefficient of the chemical (Freeze and Cherry 1979).

2.3 Mechanical Dispersion

Mechanical dispersion refers to the spreading of the contaminant plume that occurs due to variations in the flow velocity. In the saturated zone, velocity variations occur due to a variety of factors, including inter-pore and intra-pore velocity variations and the tortuosity of the porous media. The net effect of mechanical dispersion is that the chemical spreads both horizontally and vertically, thus reducing the overall concentration in the plume. Thus, like diffusion, dispersion is a dilution process.

The transport of mass due to mechanical dispersion is quantified using Fick's Law. The key parameters are the dispersivity coefficients in the three cardinal (x, y, and z) directions. Dispersivity values have been measured using tracers at several research sites, based on which empirical dispersivity relationships have been developed (EPRI 1985; Xu and Eckstein 1995). For most site-specific applications of fate and transport models, these empirical relationships are used. Higher dispersivity values result in larger plumes, which result in increased dilution and lower concentrations.

2.4 Hydrodynamic Dispersion

The term hydrodynamic dispersion refers to the sum of molecular diffusion and mechanical dispersion. In most ground water systems where there is advection, hydrodynamic dispersion is approximately equal to mechanical dispersion, since the effect of molecular diffusion is negligible.

2.5 Sorption

Sorption refers to the transfer or distribution of mass between the liquid and solid phases. Sorption has the overall effect of reducing the mobility of the chemical, which increases its residence time in the subsurface and hence the amount of microbial degradation. This distribution is quantified by the soil water partition coefficient. For organic chemicals, the partition coefficient depends on the chemical-specific normalized organic carbon partition coefficient and the organic carbon content in the soil. The partition coefficient is used to estimate the retardation factor for the chemical, which is a measure of the "stickiness" of the chemical to the formation. Parameters required to estimate the retardation factor include porosity, organic carbon content of soil, bulk density of soil, and chemical-specific normalized organic partition coefficient.

2.6 Volatilization

Volatilization refers to the transfer of chemical from the LNAPL or dissolved phase to the vapor phase. Vapors can migrate by diffusion alone (in the absence of a pressure gradient) and by diffusion and advection if a pressure gradient exists in the formation. Chemicals volatilizing from the dissolved plume occupy the pores in the unsaturated zone and migrate outwards due to the combined influences of molecular diffusion and vapor-phase advection if pressure gradients exist. Thus, volatilization can result in a net loss of chemical from the dissolved phase or from the LNAPL.

The chemical-specific factors controlling volatilization from a dilute solution and LNAPL are the Henry's Law constant and saturated vapor pressure, respectively. These factors are sensitive to the temperature of the media where volatilization occurs.

2.7 Biodegradation

Biodegradation refers to the destruction of chemicals by indigenous microorganisms present in the aquifer. For petroleum hydrocarbons, biodegradation is the primary

destruction mechanism. Due to the significance of biodegradation within the overall process of NA, biodegradation is discussed at length in section 3. In certain situations, additional compounds (e.g., ozone, oxygen, peroxide); nutrients; or microorganisms may be added to the contaminant plume to enhance the rate of biodegradation.

2.8 Overall Effect of Natural Attenuation Processes

As explained above, the process of NA refers to a combination of advection, molecular diffusion, dispersion, sorption, volatilization, chemical reactions, and biodegradation.

The combined effect of these processes is to spread or reduce the chemical mass in the dissolved plume. Thus, the concentration of the chemical decreases as distance from the source increases. Figure 2 shows the concentration profiles in actual monitoring wells down-gradient of a source and the expected concentrations under ideal conditions. Although such patterns have been observed at several sites, fluctuations in water levels, flow direction, and climatic conditions often result in nonideal behavior. Additional complications occur due to errors in data collection, analytical measurements, and the existence of multiple sources (in space and time) at a site.

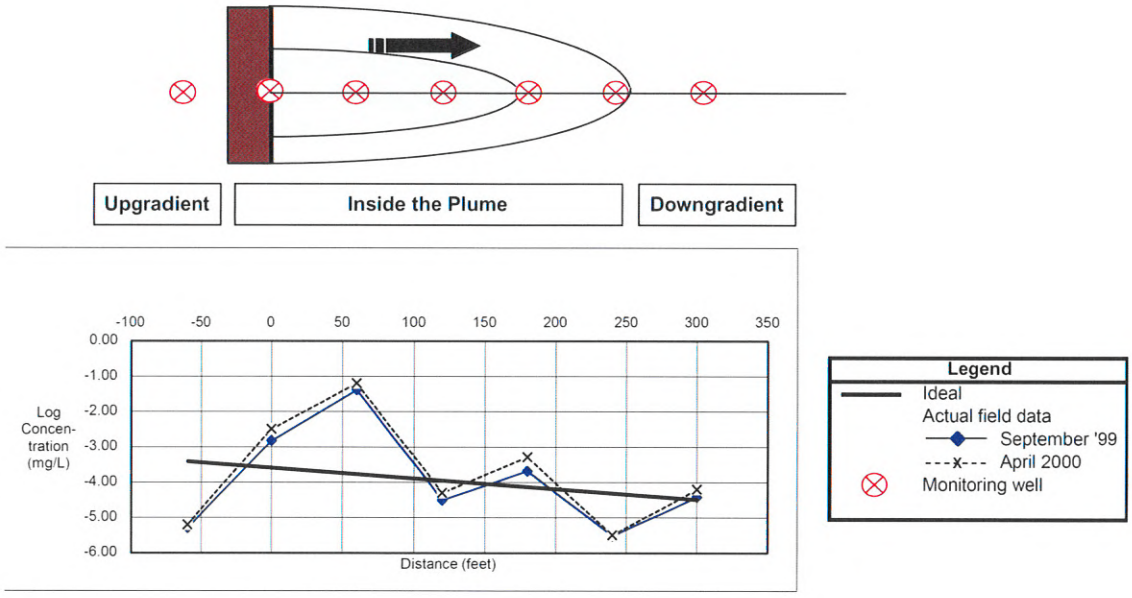

Figure 2. Concentration profile as a function of distance (ideal behavior and data from an actual site)

Depending on the overall rate of NA and the on-going contribution of chemicals to the ground water plume from the residual soil source, ground water plumes may be classified as expanding, stable, or shrinking. These concepts are discussed below.

2.8.1 Expanding Plume

An expanding plume is characterized by increasing concentrations within the plume and/or an outward movement of the plume that increases the size of the plume. An expanding plume occurs when the chemical mass loading to the plume from leaching or dissolution of residual LNAPL exceeds the mass loss due to NA processes.

In an expanding plume, NA processes continue to occur but at a rate too slow to prevent the increase in concentrations or the size of the plume.

2.8.2 Stable Plume

A stable plume is characterized by stable concentrations within the plume and at the periphery of the plume (i.e., the concentrations do not show a decreasing or increasing trend). For a plume to be stable in size or concentration, the rate of chemical mass addition to the plume from the source is equal to the rate of chemical mass loss by NA processes. The source may be the chemicals leaching from adsorbed and residual concentrations in the capillary/water table fluctuation zone or in the vadose zone or the dissolution of chemicals from the LNAPL source.

2.8.3 Shrinking Plume

A shrinking plume is characterized by decreasing ground water concentrations within the plume, decreasing concentrations at the periphery of the plume, or a decrease in the area of the plume. For a shrinking plume, the addition of chemical mass from the source is less than the mass lost due to NA processes. Thus, unless site-specific conditions change that result in an increase in chemical mass addition to the plume or a decrease in the rate of NA, the plume will eventually disappear.

2.8.4 Lifecycle of a Plume

Initially, when a chemical reaches the ground water and a plume forms, it is an expanding plume. The plume continues to expand as long as the addition of chemical mass from the source exceeds mass loss by NA processes. As the plume expands and occupies an ever-increasing portion of the aquifer, the loss of mass by NA processes increases. Thus, a point is reached when the mass addition equals mass lost, and the plume becomes stable. Because of the phenomenon of NA, most BTEX plumes resulting from service station spills become stable at lengths less than 500 feet, as demonstrated by numerous plume studies (Buscheck et al. 1996; Rice et al. 1995). At most sites, the chemical source is finite; in time, the mass loading from the source to the dissolved plume decreases. Meanwhile, the rate of mass loss due to NA processes increases or stays the same, so eventually the plume begins to shrink.

Under ideal conditions, all dissolved chemical plumes would follow the above lifecycle; however, real plumes may not follow this pattern due to a number of confounding factors, including the following:

- Variations in ground water velocities that affect the rate of NA
- Fluctuations in the water table that affect the source mass loading due to the release of chemicals trapped in the capillary fringe
- Variations in climatic conditions that affect the rate of NA
- Variations in rainfall and infiltration that affect mass loading to ground water
- Additions to the plume from new releases and spills from operating facilities

Because of the above complications, it is important to collect and evaluate all the site data and look at multiple lines of evidence to understand the plume behavior and predict its future behavior (see section 3.5).

3 Biodegradation of Petroleum Hydrocarbons

This section discusses the biodegradation of dissolved petroleum hydrocarbons and identifies the various indicators that should be measured to confirm biodegradation.

The biodegradation of hydrocarbons is the process by which naturally occurring subsurface microorganisms biodegrade contaminants. The process of biodegradation, as facilitated by microorganisms, can be represented by the general reaction:

Hydrocarbon + Electron Acceptors + Nutrients YIELDS *Carbon Dioxide + Water + Microorganisms + Waste Products*

The above biologically mediated reaction produces energy for cell growth and reproduction of the microbial population. The process of electron transfer results in the oxidation of the donor (hydrocarbon), reduction of the electron acceptor, and the production of usable energy for the organisms. Based on the principles of thermodynamics, biologically mediated reactions that yield the most energy are favored over reactions that yield less usable energy for the organisms. For hydrocarbons, biologically mediated reactions ideally occur in the following order:

1. Dissolved oxygen in the ground water is used as the electron acceptor.
2. After all oxygen has been depleted and anaerobic conditions exist within the dissolved plume, dissolved nitrate is used as the electron acceptor.
3. After the depletion of dissolved oxygen and nitrate, ferric iron is used as an electron acceptor and is reduced to ferrous iron.
4. After the depletion of oxygen, nitrate, and iron, sulfate is used by sulfate-reducing bacteria to degrade the hydrocarbons.
5. Finally, methanogenesis degrades the hydrocarbons.

While all petroleum hydrocarbons are biodegradable, the rate of biodegradation can differ significantly from site to site depending on the composition and amount of hydrocarbons; type and amount of available electron acceptors; type, number, and characteristics of the microorganisms; and quantity and quality of nutrients.

Site-specific measurements of these factors, comparison of these factors within and outside the plume, and temporal variations in these factors can be used to demonstrate the occurrence of biodegradation. Each of these factors is discussed below.

3.1 Composition and Amount of Hydrocarbons

Almost all petroleum hydrocarbons are biodegradable under aerobic conditions. The ease of biodegradation depends on the type of hydrocarbon. Low molecular weight hydrocarbons (e.g., C10 to C24 alkenes) and single-ring aromatics are the most easily biodegradable. As molecular weight increases, resistance to biodegradation also increases. Individual compounds degrade at different rates under aerobic and anaerobic conditions.

For most hydrocarbon-impacted sites, the primary chemicals of interest (from a risk perspective) are BTEX, MTBE, and naphthalene. Naphthalene and BTEX are readily degradable under aerobic conditions. Benzene typically degrades slower than other BTEX hydrocarbons under anaerobic conditions. The biodegradation and NA of MTBE has been a topic of current research (Moyer and Kostecki 2003; EPA 2005; API 2007). MTBE degrades under both aerobic and anaerobic conditions. However, the rates of MTBE degradation and controlling factors have not yet been firmly established.

3.2 Available Electron Acceptors

The biodegradation of hydrocarbons is essentially an oxidation-reduction reaction. In this reaction, the hydrocarbon donates the electron (i.e., the hydrocarbon is oxidized) and a second compound (the electron acceptor) is reduced. Of the several electron acceptors available in the subsurface environment, oxygen, because of its high energy yield, is typically used first by microorganisms. Anaerobic bacteria can use other electron acceptors, including the following:

- Nitrate (NO_3^-) that is reduced to nitrogen (N_2)
- Manganese (Mn^{4+}) that is reduced to water soluble Mn^{2+}
- Ferric iron (Fe^{3+}) that is reduced to water soluble Fe^{2+}
- Sulfate (SO_4^{--}) that is reduced to sulfide (S^-)
- Carbon dioxide (CO_2) that may be used by methanogens to yield methane (CH_4)

As the biodegradation of hydrocarbons occurs, the concentration of the electron acceptors decreases and the concentration of the products formed increases. This concept can be used to demonstrate the occurrence of biodegradation (i.e., secondary line of evidence, see section 3.5.2). Table 1 shows the expected relationship between the BTEX concentration and the electron acceptors and the products of the oxidation reduction reaction.

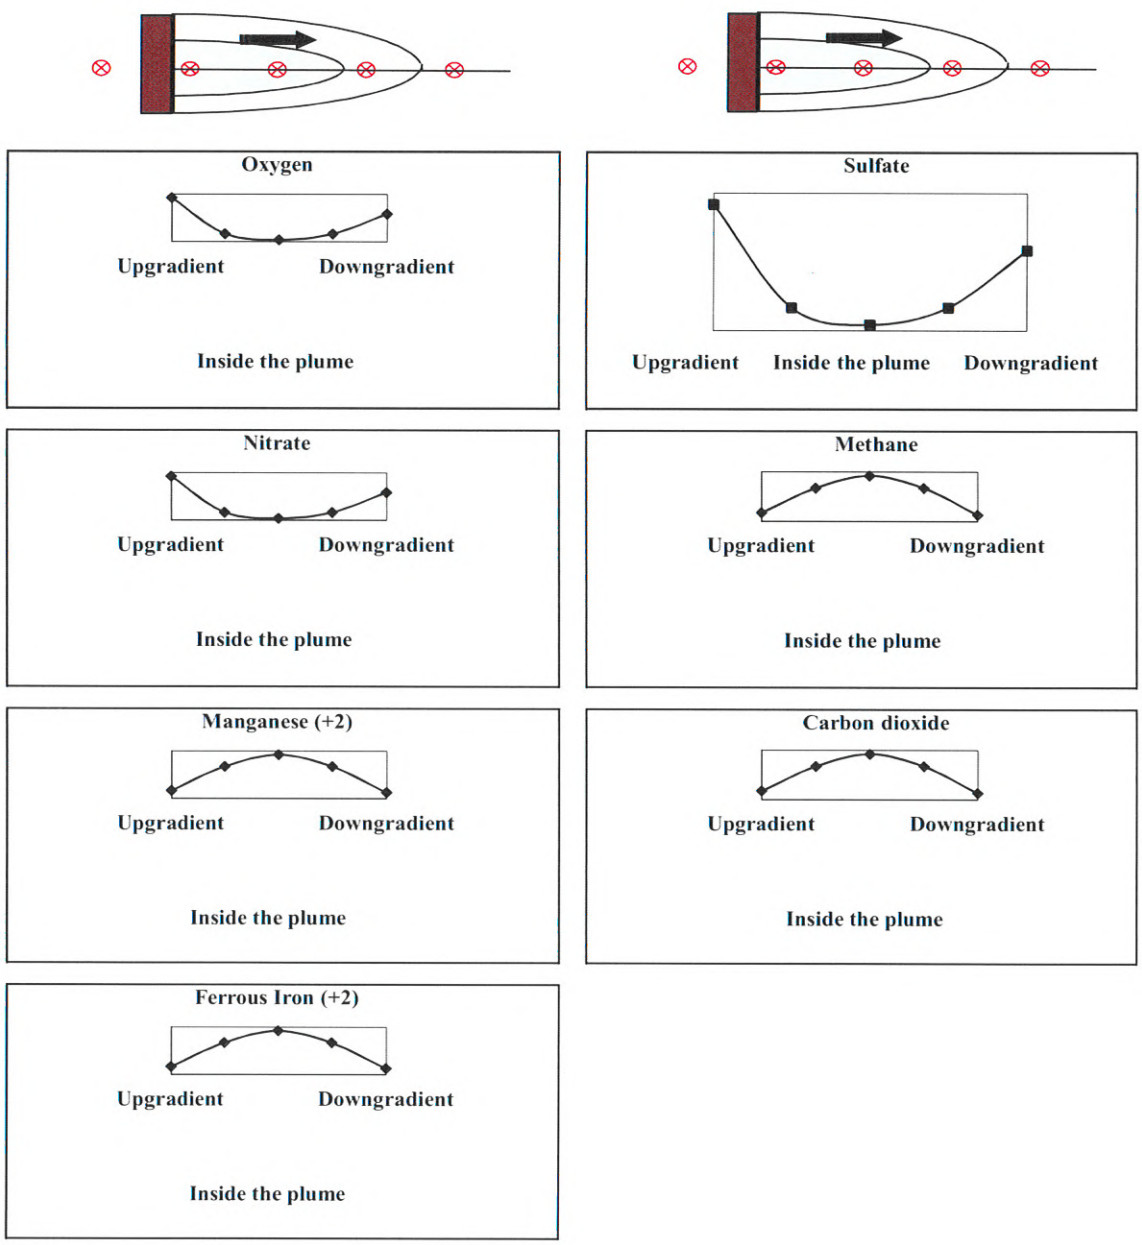

Figure 3. Expected pattern of natural attenuation indicators (secondary line of evidence)

3.3 Quantity and Quality of Nutrients

In addition to the electron acceptors, microorganisms also require nutrients. These nutrients are incorporated into the biomass and are necessary to form cells. The nutrients nitrogen and phosphorous are required in relatively large amounts. Small amounts of micro-nutrients—such as sulfur, manganese, and magnesium—are also required.

Certain compounds, such as nitrates and sulfates, can serve either as nutrients or electron acceptors. Nutrients are rarely a limiting factor in the subsurface biodegradation of petroleum hydrocarbons. A decrease in nutrient levels within the zone of degradation can indicate biodegradation.

3.4 Characteristics of Microorganisms

The ability of microorganisms to degrade a wide variety of petroleum hydrocarbons is well documented. Hydrocarbon-degrading microorganisms are widespread in the environment, as they occur in fresh water, salt water, soil, and ground water. The number of cells per milliliter of water can also be used as an indicator of biodegradation. As hydrocarbons degrade, the cell count for hydrocarbon-degrading bacteria increases. McKee et al. (1972) found 50,000 or more hydrocarbon-degrading bacteria per milliliter of water in samples from wells containing traces of gasoline, while a noncontaminated well had only 200 microorganisms per milliliter.

3.5 Indicators of Natural Attenuation of Hydrocarbon Plumes

Based on the information presented above, concentrations of several substances (hydrocarbons, electron acceptors, microorganisms, nutrients, and carbon dioxide) can be measured to demonstrate the occurrence of NA.

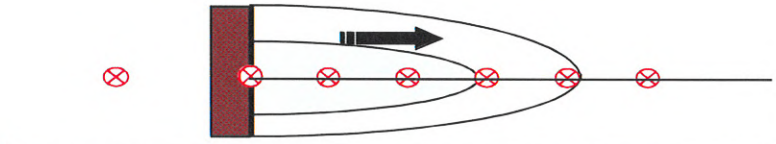
These measurements are typically divided into three tiers, or "lines of evidence" (i.e., primary, secondary, and tertiary lines of evidence), to demonstrate NA. Data collected under each line of evidence can be evaluated qualitatively or quantitatively.

3.5.1 Primary Line of Evidence

The purpose of the primary line of evidence of NA is to demonstrate the loss of chemical mass by evaluating measured petroleum hydrocarbon concentrations. Of all the methods available to demonstrate the occurrence of NA, this is perhaps the simplest and most useful to demonstrate site-specific reductions in risk. Site-specific application of the primary line of evidence requires an adequate number of correctly installed sampling points (monitoring wells), an adequate amount of chemical data from these points, and a thorough evaluation of these data. These issues are discussed in Parts II and III of this document.

Although the primary line of evidence can show whether the concentration of a plume is attenuating, it does not show whether the decrease is due to destructive mechanisms or merely dilution. Secondary lines of evidence are necessary to determine whether the decrease is due to biodegradation.

3.5.2 Secondary Line of Evidence



Secondary evidence of NA refers to measurements of electron acceptors and products of metabolism within the plume and their comparison with concentrations in the unimpacted area of the aquifer, where no biodegradation activity would be expected to occur.

Parameters that are typically measured in the field include dissolved oxygen, REDOX potential, dissolved nitrates, manganese, ferrous iron, sulfate, and methane. These parameters should be measured at up-gradient locations, inside the plume near the source, and at down-gradient locations. Expected patterns of these parameters that are indicative of biodegradation are shown in Table 1 and Figure 3.

As microorganisms consume chemicals, there is a corresponding consumption of the compounds that serve as electron acceptors. Thus, the concentration of these compounds would decrease in the portion of the plume where biodegradation is occurring. For example, under aerobic biodegradation, the concentration of oxygen would decrease, assuming oxygen is not being added to the plume. Similarly, under anaerobic conditions, a depletion of nitrate, ferric (III) iron, and sulfate can be expected.

Biodegradation also results in an increase in the concentration of metabolic byproducts. For example, increased concentrations of nitrite and ferrous (II) iron within the plume would be indicative of biodegradation.

Table 1. Expected pattern of natural attenuation indicators (secondary line of evidence)

	Upgradient	Inside the plume		Downgradient
BTEX	ND	High	Low	ND

Type of Reaction	Geochemical Indicator	Geochemical Indicator Concentration		
Aerobic	Oxygen	High	Low	High
Anaerobic	Nitrate	High	Low	High
	Manganese	Low	High	Low
	Ferrous Iron	Low	High	Low
	Sulfate	High	Low	High
	Methane	Low	High	Low
	Carbon dioxide	Low	High	Low

The secondary line of evidence demonstrates the occurrence of biodegradation only. It does not provide any data on the occurrence of other NA processes.

3.5.3 Tertiary (Optional) Line of Evidence

The tertiary (optional) line of evidence involves performing microbiological studies, such as identifying the microorganisms present in the formation and counting their cells, in an effort to demonstrate the occurrence of NA. Thus, the objectives of secondary and tertiary lines of evidence are similar. In the portion of the plume where NA is occurring, the ratio of petroleum degraders to the total number of bacteria should be higher than in

the uncontaminated portion of the plume due to the readily available petroleum energy source. Tertiary lines of evidence are seldom required at petroleum hydrocarbon impacted sites and are not discussed further.

PART II: Process for the Implementation of Remediation by Natural Attenuation

Remediation by natural attenuation refers to the achievement of site-specific cleanup goals using NA. As discussed in Part I, NA consists of several processes that occur at all contaminated sites at varying rates. As with any other remedial option, the site-specific applicability of RNA must be carefully evaluated before it is selected as the remedial alternative of choice. RNA should not be considered a presumptive remedy; rather, it is one of several available strategies that should be evaluated to ensure its applicability based on site-specific conditions.

The first step in any evaluation of NA is the collection of appropriate site characterization data. In general, the data collected need to confirm the occurrence of NA, the effectiveness of RNA, and that the receptors are not exposed to unacceptable risk throughout the period when the site is being remediated by NA. The data collected should help answer the following questions and support the activities described in the questions.

- Has the full horizontal and vertical extent of the source and the plume been delineated?
- Is the plume at steady state and is it stable or shrinking in size?
- Can contaminant degradation be demonstrated and quantified?
- Can the long-term behavior of the source and the plume be modeled?
- Can the time frame to achieve remedial cleanup goals be estimated?
- What is the impact of source removal/reduction on the remedial time frame?

Once the site has been characterized to document the feasibility of NA, an evaluation as to the site-specific appropriateness of NA as the preferred remedy should be performed. RNA is applicable only at the following types of sites:

- Sites where immediate threats to human health, safety, and the environment do not exist or have been mitigated
- Sites where "active" sources, such as leaking tanks, drums, etc., have been removed
- Sites where the projected time frame to achieve remedial objectives is "reasonable," as defined in section 7
- Sites where the plume is stable or shrinking and is not likely to impact current receptors or sensitive habitat
- Sites where active remediation has removed the bulk of the contaminants and the role of RNA is to perform the "final touchup"
- Sites where any necessary institutional controls can be reliably implemented

Upon selection of RNA as part or all of the preferred remedy, a corrective action plan will be developed to document the selection process and provide details about implementation of the remedy. The Idaho Department of Environmental Quality (DEQ) must approve this corrective action plan. At all sites, RNA will be accompanied by long-term monitoring to demonstrate that RNA is occurring at the rate anticipated when RNA

was selected as the remedial option. Monitoring will continue until the specified cleanup goals have been achieved. If the monitoring data indicate that RNA is not occurring at an acceptable rate, the remedial plan will need to be modified.

4 Risk Management Plan for Remediation by Natural Attenuation

At sites where RNA is part of the preferred remedial option, the responsible party should include a discussion in the corrective action plan that addresses the following elements:

- A summary of site characterization activities that demonstrates a thorough understanding of the nature and extent of the source and the nature and extent of the impacts, provides data supporting the likely effectiveness of RNA, and discusses any source removal/control activities performed at the site
- A discussion of remedial endpoints and points of compliance, and the manner in which these were determined
- A discussion of the time frame over which the endpoints are expected to be achieved
- A demonstration that during this time frame, risks to human health and the environment are acceptable
- A discussion of monitoring locations, the rationale for monitoring location selection, and the type and frequency of data that will be collected to monitor the performance of RNA and the achievement of remedial goals
- A description of the tools to be used to evaluate/analyze the monitoring data
- A description of the institutional controls that may be required and documentation of their implementation
- A description of a contingency plan that will be implemented if the monitoring results indicate that RNA is not sufficiently effective or is not proceeding at the expected rate
- A description of the frequency and form of the reports to be submitted to DEQ during the course of implementing RNA

A brief discussion of critical components of the RNA portion of the corrective action plan is presented below.

5 Source Characterization and Control

Characterizing and controlling the source are important aspects of RNA. Sufficient data should be collected during the site investigation phase to delineate the nature and extent of the source and estimate the source lifetime. The term "nature" refers to an evaluation of the chemicals of interest and a determination that the chemicals are amenable to NA. The extent refers to the physical dimensions of the source as well as a determination of the mass of residual chemicals present in the source. An estimate of the lifetime of the source can be made by calculating the mass flux out of the source area (using ground water flow characteristics and contaminant concentrations in the source area) and

comparing this to the total contaminant mass in the source area (including free phase product, soils, and ground water).

DEQ requires that all active sources (e.g., leaking pipes, tanks, spills) be stopped and any free phase product in ground water be removed, to the maximum extent practicable. It is best to reduce the source and remediate soils containing residual product that are significant sources of contamination to ground water. Such control measures will reduce the time required to achieve remedial objectives. At a minimum, sufficient source material should be removed to ensure a declining plume. The amount of active remedial activity necessary should be determined on a case-by-cases basis and clearly presented in the risk management plan.

6 Plume Characterization

The goals of collecting data to characterize the plume are to demonstrate the magnitude and direction of contaminant transport and the stability status of the plume, to confirm degradation is occurring, and to estimate the contaminant degradation rate or the ability of the aquifer to assimilate the contamination.

To achieve these goals, the responsible party must construct wells to account for aquifer heterogeneity and dominant zones of contaminant transport, select appropriate monitoring locations, collect samples at an adequate frequency, and collect and evaluate the appropriate analytical data. How to determine the appropriate monitoring locations, sampling frequency, and data is discussed below.

The location and number of ground water samples collected and analyzed must be determined based on site-specific conditions.

At a minimum, sampling points should be located so as to achieve the following:

- Locate the distribution of contaminants within the plume
- Locate the plume boundaries
- Track plume movement and migration

While they do help define the extent of the plume, sampling points at nondetect locations provide little useful information for documenting plume characteristics for an NA evaluation. Most sampling points need to be located within the plume boundaries for NA evaluation purposes.

Monitoring wells should be located up-gradient of the source, within or immediately down-gradient of the source area, and within the plume aligned along the plume axis. Data should be collected from an unimpacted down-gradient well also. A down-gradient clean well can be used to help characterize the extent of the plume and may be used to protect down-gradient receptors by providing early detection of plume movement. This function is described in section 8. Wells delineating the sides of the plume assist in determining if there are significant seasonal changes in ground water flow direction.

As discussed in sections 3.5.1 and 3.5.2, data related to the primary and secondary lines of evidence should be collected. In rare cases, it may be necessary to collect data to demonstrate tertiary lines of evidence as well. Based on the data collected, a determination should be made whether the plume is expanding, stable, or shrinking. The specific analytical tools that may be used to conduct this characterization are discussed in Part III of this document.

Expanding plumes require continued monitoring. Depending on site conditions, such as the risk to current or potential future receptors and the rate at which the plume is expanding, additional assessment of the plume and/or source removal and reduction may be necessary. An expanding plume typically requires active remediation.

Plumes documented to be stable or shrinking are candidates for the use of NA. These plumes will also require continued monitoring, though perhaps at a lower frequency than expanding plumes. Depending on site conditions and the time frame of remediation, a stable plume may require residual source characterization or removal.

The frequency and duration of monitoring during the plume characterization phase should be determined on a site-specific basis and in consultation with DEQ. However, in most cases, 1–2 years of quarterly monitoring data are necessary to evaluate the degree of seasonal variations in water levels and flow directions present at a site. This information is necessary to characterize a plume as expanding, stable, or shrinking and to estimate degradation rates. As clear trends emerge in the data, the monitoring frequency may be modified. The actual duration of sampling will depend on the time it takes to demonstrate a clear trend in the concentrations.

7 Reasonable Time Frame Determination

The determination as to what constitutes a reasonable time frame for RNA is a complex, site-specific determination not amenable to simple rules of thumb or quantification. In making this determination, DEQ will take into account factors that include, but are not limited to, the following:

- The time frame for RNA compared to that for other remedies being evaluated
- The time frame in which affected portions of the aquifer might be needed for various uses
- The likelihood that impacted ground water will be utilized
- The degree of uncertainty in site characterization and NA estimates
- The reliability of institutional controls over the time frames for which they may be required to function
- The ability of the responsible party to maintain the required monitoring and plume evaluation required when NA is used as a remedy

8 Monitoring to Demonstrate the Effectiveness of Remediation by Natural Attenuation

Due to the uncertainties associated with the site-specific implementation of RNA, long-term monitoring is necessary to demonstrate its effectiveness. Long-term monitoring is used to ensure that the behavior of the plume does not change (EPA 1999) and that predictions of plume behavior are accurate. The objectives of long-term monitoring are to demonstrate NA is continuing to occur, human health and the environment are being protected, and the plume is not expanding.

The specifics of the monitoring plan (e.g., the location, frequency, and type of samples to be collected and the analytical procedures to be used) should be determined on a site-specific basis. The primary factors that should be considered when designing a long-term monitoring program include the following:

- Distance to potential receptor exposure points
- Ground water seepage velocity and direction
- Types of contaminants
- Aquifer heterogeneity
- Three-dimensional distribution of chemicals of interest
- Areas of unique geochemical conditions
- Surface water impacts
- Effects of active remediation systems (Wiedemeier et al. 2000)

The secondary factors that should be considered include the following:

- Access issues
- Property lines
- Contaminant contributions from offsite sources (Wiedemeier et al. 2000)

Two types of wells are required for any long-term monitoring program: performance monitoring wells and contingency monitoring wells. Performance monitoring wells are used to demonstrate that NA is proceeding according to expectations; document that geochemical conditions continue to be adequate to support NA processes; identify any toxic products resulting from NA processes; determine if plume conditions remain stable or are shrinking; identify changes in ground water conditions, such as change in flow direction, recharge, etc.; and document that cleanup criteria have been met.

Contingency monitoring wells are placed beyond the predicted down-gradient boundary of the plume and up gradient from known or potential receptor exposure points. Their purpose is to provide an "early-warning" if unexpected plume expansion occurs and allow implementation of a contingent remedy if needed. Multiple contingency wells may be needed, particularly if seasonal variations in ground water flow direction are known to occur.

Sampling frequency should be based on the following factors:

- The natural variability observed in contaminant concentrations
- The distance and travel time from the source to the point of compliance
- The reduction in concentrations needed to meet target levels

9 Contingency Measures

The RNA corrective action plan should include a contingency plan to be implemented if the site data indicate that RNA is not occurring at the expected rate or the exposure conditions at the site have changed, resulting in an unacceptable risk to human health or the environment.

Contingency measures will prevent delays in site remediation and provide a clear roadmap for site remediation. Triggers should be established and included in the plan that would cause the responsible party to implement alternative active strategies to enhance RNA. The triggers should be as objective and quantitative as possible. Examples of triggers that would cause the responsible party to implement alternative strategies include, but are not limited to, the following:

- A consistent increase in concentrations in one or more wells
- A failure of any of the institutional conditions necessary to protect human health and the environment during the period of RNA
- A change in the exposure conditions (e.g., removal of pavement)
- Continued expansion of the plume
- Unacceptably low rates of RNA

PART III: Techniques Available to Demonstrate Natural Attenuation

Several techniques are available to evaluate the data collected to demonstrate NA or to design and implement an RNA program. These techniques can be divided into three categories: techniques to demonstrate the occurrence of NA, techniques to estimate the site-specific rate of NA, and techniques to quantify the future behavior of the plume. The available techniques for each of these evaluations are presented below.

10 Techniques to Demonstrate the Occurrence of Natural Attenuation

The occurrence of NA may be demonstrated by using graphical and/or statistical techniques. The specific techniques used will vary depending on site conditions and the specifics of the data. To the extent possible, multiple techniques should be used to provide added insight into the NA process.

10.1 Graphical Techniques

Chemicals-of-interest data collected from strategically located monitoring wells can be used to draw site-wide contour maps of individual constituent concentrations for each monitoring event, create concentration-versus-time plots for each well with detectable constituent levels and at least four rounds of data, and create concentration-versus-distance plots along the flow direction for several monitoring events. Depending on the variability in the concentrations, it may be better to plot the natural logarithm of concentration versus time and distance. An example plot is shown in Figure 4. When creating these plots, care should be taken to ensure that the selected scale clearly demonstrates the trend. Since the concentrations are affected by water level fluctuations, it is important to also plot water levels as a function of time.

These plots can indicate whether the concentration trend is decreasing, stable (no significant trend), increasing, or mixed. The latter refers to a situation where different wells (source wells versus periphery wells) exhibit different trends. Increasing concentrations in the source well and decreasing concentrations in the down-gradient wells may occur due to a variety of reasons. For example, the mass loading to the source may cause an increase in the source wells due to an increase in the infiltration rate, or the rate of biodegradation near the source may be reduced due to a depletion of oxygen.

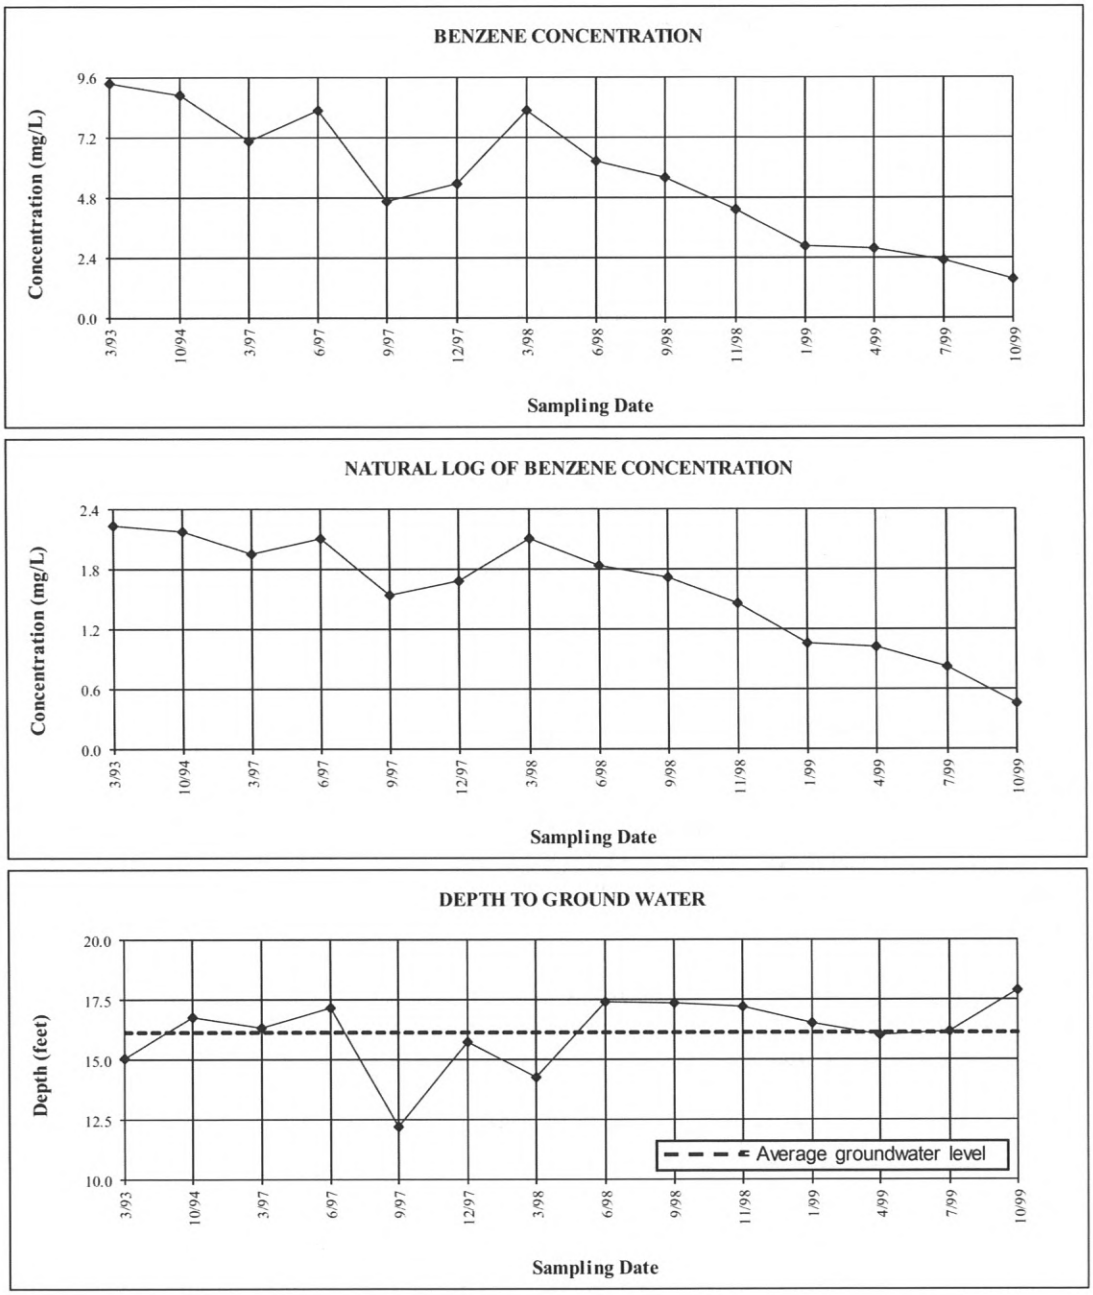


Figure 4. Concentration-versus-time plot of benzene

Conversely, increasing concentrations in down-gradient wells and decreasing concentrations near the source may indicate that the plume is moving but the source has depleted. Conclusions related to concentration trends based on visual observations of the data must be supported by statistical analysis.

In addition to the chemical-of-interest concentrations, indicator chemical concentrations should be plotted along the plume axis (in the concentration-versus-distance plots) along with the hydrocarbon concentrations. The observed pattern of concentrations can be used

to demonstrate NA. For example, low dissolved oxygen concentrations within the plume and higher concentrations up-gradient and down-gradient of the source are indicative of biodegradation within the plume.

10.2 Statistical Evaluations

Statistical tools may be used to determine and quantify the concentration trend. These tests can be used to test a null hypothesis and an alternative hypothesis. A null hypothesis might be that there is no time trend in the concentrations-versus-distance or time, and the alternative hypothesis might be that there is a downward trend. Application of the statistical test would then result in accepting or rejecting the null hypothesis at a specified level of significance.

A nonparametric test, called the Mann-Kendall test, is often used to determine whether a trend exists in the data. This test is particularly useful for environmental data for several reasons:

- The test is nonparametric, which implies that the test is applicable irrespective of the underlying distribution of the data.
- The test is simple to implement.
- Concentration values below the detection limit can be used.
- The results are not affected by missing data.

The Mann-Kendall test is applicable only when there is no seasonality in the data. This is the case if the data do not show any seasonal variations or the data were collected from one season. When data indicate seasonality, the seasonal Kendall test may be used. For details on both of these tests, refer to Gilbert (1987), Gibbons (1994), or other books on statistical analysis.

DEQ strongly recommends the use of the Mann-Kendall test to determine the trend in nonseasonal data except in situations where a visual plot of data indicates without **any** ambiguity that a trend exists in the data.

If the concentration-versus-time or concentration-versus-distance data indicate a decreasing trend, a regression analysis may be used to estimate the slope of the best-fit line.

As explained in section 11.2 and 11.3, the slope of the line can be used to estimate the NA or the biodegradation rate. For additional information on regression analysis, refer to any statistics textbook.

11 Techniques to Estimate the Site-specific Rate of Natural Attenuation

The data collected to demonstrate the primary line of evidence of NA can be used to estimate site-specific NA rates and biodegradation rates. Since NA includes multiple processes in addition to biodegradation, the NA rate would be higher than the

biodegradation rate. The latter can be used as an input into a ground water fate and transport model, such as Domenico's model (Domenico 1987), to estimate the future migration of the plume, and to estimate a site-specific dilution attenuation factor. Three methods are available to estimate the NA rate: 1) mass balance analysis for expanding, stable, or shrinking plumes; 2) plume concentration-versus-time plots; and 3) plume concentration-versus-distance plots. Descriptions of each of these methods are presented below. An excellent discussion of the calculation and use of rate constants for use in NA evaluations is presented in EPA (2002). This section also includes a discussion of calculating biodegradation rates using recalcitrant tracers.

11.1 Mass Balance Analysis

This method of estimating the NA rate is based on the concept of mass balance. For a stable plume, the mass entering the ground water plume must equal the mass lost by NA. Thus, if the mass entering the plume can be estimated, it should be possible to estimate the NA rate. A detailed description of the application of mass balance analysis to estimate the NA rate of a petroleum release is described in Section X6.1 of the *Standard Guide for Remediation of Groundwater by Natural Attenuation at Petroleum Release Sites* (ASTM 2004).

11.2 Well Concentration-versus-Time Plot

The estimate of the overall attenuation rate for a shrinking plume can be calculated assuming a first-order decay rate and is represented mathematically by Equation 1:

$$\frac{dC}{dt} = exp^{(-kt)} \qquad \text{(Equation 1)}$$

Where:
C = concentration
t = time [years]
k = NA rate [1/yr]

The solution to the above differential equation results in the familiar exponential decay equation (Equation 2):

$$C(t) = C(t=0)\,exp^{(-kt)} \qquad \text{(Equation 2)}$$

Where:
$C(t)$ = Concentration at any time t (mg/L)

Taking the natural logarithms of both sides of Equation 2 results in Equation 3:

$$ln\,C(t) - ln\,C(t=0) = -kt \qquad \text{(Equation 3)}$$

Thus, a plot of natural log of concentration versus time would be a straight line with a slope equal to k (the NA rate).

11.3 Well Concentration-versus-Distance Plot

Advective travel time can be expressed as below (Equation 4):

$$t = \frac{x}{v} \qquad \text{(Equation 4)}$$

Where:
x = Advective travel distance (cm)
v = Seepage velocity (cm/yr)

Substituting Equation 4 in Equation 2 results in Equation 5:

$$C(t) = C(t=0)\,exp^{(-k\frac{x}{v})} \qquad \text{(Equation 5)}$$

Taking the natural log of both sides of the equation results in Equation 6:

$$ln[C(t=0)] - ln[C(t)] = -k\frac{x}{v} \qquad \text{(Equation 6)}$$

For a shrinking plume that follows the first-order attenuation rate presented above, a plot of log concentration versus distance would be a straight line with a slope of k/v. By multiplying the slope with the seepage velocity, the NA rate (k) can be estimated.

Buscheck and Alcantar (1995) used the solution of the one-dimensional transport equation with biodegradation to estimate the biodegradation rate based on the slope of the log concentration-versus-distance plot. Specifically, they derived the following expression (Equation 7) for the biodegradation rate:

$$\lambda = \frac{v}{4\alpha_x}\left\{\left[1+2\alpha_x\left(\frac{k}{v}\right)\right]^2 - 1\right\} \qquad \text{(Equation 7)}$$

Where:
λ = Biodegradation rate, assumed to occur at equal rates in the dissolved and sorbed phases
α_x = Longitudinal dispersivity (0.1x)

Zhang and Heathcote (2003) modified this method to account for situations with finite source size and lateral dispersion to improve the estimates of the biodegradation rate.

The following step-by-step description of the biodegradation rate estimation process can be implemented on a site-specific basis.

Step 1: Determine the ground water flow direction based on the water level measurements for each monitoring event.

Step 2: For each monitoring event, identify the wells located along the direction of flow (i.e., along the plume center line). Since the flow direction may vary seasonally, different wells may be used for different monitoring events.

Step 3: Tabulate the concentrations of the chemicals of interest and calculate the natural log concentrations.

Step 4: Plot the natural log concentrations on the *y*-axis and the distance along the *x*-axis.

Step 5: Calculate the slope of the best-fit line and the confidence in this estimate by examining the 95% confidence limits of the slope.

Step 6: Estimate the ground water seepage velocity.

Step 7: Multiply the slope of the best-fit line calculated in Step 5 with the seepage velocity. The result will represent the overall NA rate. This NA rate represents the reduction in concentration due to the combined influence of the various NA processes mentioned in section 2. This decay rate should not be confused with the biodegradation rate (λ) that is an input to ground water models.

Step 8: Estimate the biodegradation rate from Equation 7.

Steps 1–8 should be completed for each time period for which data are available and the results presented as a range of NA and biodegradation rates. The latter can be used as an input to the Domenico model (Domenico 1987) to estimate the dilution attenuation factor. Due to confounding factors such as seasonal variations in ground water velocity, fluctuations in water levels, and errors in sampling and analysis methods, the NA and biodegradation rates may vary significantly (by as much as a factor of 10). Therefore, it is best to present the range as well as the average rates.

11.4 Evaluation of Plume Behavior with a Recalcitrant Tracer

Physical, chemical, and biological processes act together to decrease contaminant concentrations away from a source. However, monitored NA requires that accurate biodegradation rates for a site be known. To estimate accurate biodegradation rates, conservative tracers can be employed. The concentrations of these tracers are not affected by biodegradation processes and so can be used to delineate between the effects of biodegradation and other NA processes such as dilution and sorption. Generally, tracers are biologically recalcitrant and have chemical properties similar to the contaminant of interest. Examples of common tracers include MTBE for petroleum hydrocarbon plumes.

12 Techniques to Quantify the Future Behavior of the Plume

The future behavior of the plume can be estimated by using fate and transport models. A number of analytical and numerical models are available. Commonly used analytical

models include the Domenico model (Domenico 1987) and BIOSCREEN. BIOSCREEN can be downloaded from www.epa.gov/ada/csmos/models/bioscrn.html.

These models can be used to estimate plume length, concentrations at down-gradient receptor locations, and dilution attenuation factors and can be calibrated to site-specific ground water data. The correct application of fate and transport models requires experience and specialized knowledge that is beyond the scope of this document.

Appendix K: Practical Quantitation Limits

This page intentionally left blank for correct double-sided printing.

Introduction

During the risk evaluation process when collecting media-specific chemical concentration data and establishing remediation standards, situations may arise where practical quantitation limits (PQLs) for specific chemicals and samples may exceed screening levels or site-specific, risk-based concentrations. Section 500 of IDAPA 58.01.24, Application of Risk Based Corrective Action at Petroleum Release Sites, delineates the following factors that may be used to allow the use of PQLs as remediation standards:

- Analytical method
- Method detection limit
- Sampling procedures
- Estimated risk levels
- Other

This appendix provides background on the concepts of PQLs, MDLs and Remediation Standards and provides guidance on using the above factors when a REM user is proposing PQLs as remediation standards.

Background— Practical Quantitation Limits, Method Detection Limits and Remediation Standards

What are PQLs and MDLs?

A PQL is defined in part in 58.01.24.010 as "The lowest concentration of a chemical that can be reliably quantified among laboratories within specified limits of precision and accuracy for a specific laboratory analytical method during routine laboratory operating conditions." The method detection limit (MDL) is defined as "The minimum concentration of a substance that can be reported with 99% confidence is greater than zero."

How are PQLs Derived?

PQL values are derived in a number of ways, and there is no consensus as to the process used to develop them. In some cases, they are derived as a fixed multiplier applied to the MDL value or the standard deviation of samples used to develop the MDL. The multiplier commonly ranges from 3 to 5 and may be as great as 10. In other cases, PQLs may be derived by analysis of data from actual laboratory performance studies. In these cases, PQL values are a function of analytical methods, a given laboratory's equipment, operating protocols, operating conditions, quality assurance/quality control procedures, and sampling and media considerations. Values are sometimes reported by laboratories at levels between the MDL and the PQL and are commonly qualified as estimated quantities. The closer the estimated value is to the PQL, the more confidence in the estimated value.

How did DEQ derive the PQLs and MDLs in Table 1?

For the petroleum chemicals of interest (COI) listed in the rule, the common analytical methods for soil and water employed at petroleum release sites are established by the U.S. Environmental Protection Agency (EPA) in SW-846 (EPA 2011). For soil vapor and ambient air other EPA methods are applied (EPA 1999).Table 1 lists these methods employed in the analysis of the petroleum COI along with typically achieved detection and quantitation limits.

These detection and quantitation values were obtained from sample laboratory reports for site investigations done for the Idaho Department of Environmental Quality (DEQ) at a number of sites where petroleum COI were suspected. In their method descriptions, EPA lists examples of lower limits of quantitation for individual analytes but indicates that they are instrument-dependent and influenced by sample preparation/introduction technique (EPA 2006) or highly matrix-dependent and are provided for guidance only (EPA 2007).

For a given media, sampling considerations may have an impact on achievable detection limits. For example, when sampling soil vapor or ambient air with certain methods, the achievable quantitation limit can be a function of the amount of vapor or air sampled. Quantitation limits are commonly reduced as the amount of air sampled increases.

Specialized analytical techniques can sometimes provide lower MDL and PQL values. Table 1 illustrates this with a comparison of values achieved with the use of standard method 8270 for semivolatile compounds versus employing 8270 using selective ion monitoring (SIM). PQL values are 6 times lower for soils and 20 times lower for water samples.

Depending on the petroleum product released, levels of contamination, chemicals present, and media in question (soil, water, and vapor), interferences to analytical detection and quantitation may be present. Procedures such as sample dilution may allow quantification of petroleum COI concentrations but will also result in elevated detection and quantitation limits.

Remediation Standard

A remediation standard is defined in IDAPA 58.01.24 as a "media specific concentration which, when attained, is considered to provide adequate protection of human health and the environment."

Remediation standards are established at petroleum release sites where corrective action has been determined to be required. The need for corrective action is commonly determined after completion of a risk evaluation. Remediation standards are commonly established as part of a risk evaluation or an approved corrective action plan (CAP).

The magnitude of a remediation standard that is established for a given chemical and the potential that it may be exceeded by a PQL is dependent on a number of factors, including, but not limited to, the following:

- Assumptions regarding current and future site land use, both on and off site
- What petroleum products were released and the relative distribution of chemicals detected
- The magnitude and distribution of contamination (which media are impacted)
- The routes of exposure determined to pose the greatest threats

The two risk evaluation scenarios where elevated PQL values may require the reevaluation of initially selected remediation standards are as follows:

1) Screening Level Evaluation
The screening level evaluation described in IDAPA 58.01.24 employs the simplest and most straightforward use of remediation standards in the form of the residential use screening levels. The screening levels are conservative, calculated, risk-based concentrations determined to be protective of unrestricted use exposures.

Because laboratory analytical technology is continually changing, these media-specific chemical concentrations are established without consideration of the ability of standard laboratory methods to detect and quantify these values. For the petroleum COI in Table 1, the compounds benzo(a)anthracene (BAA) and benzo(b)fluoranthene (BBF) in water and ethylene dibromide (EDB) in soil pose the greatest potential challenges with respect to PQL values meeting screening level concentrations.

For BAA and BBF, common practical quantitation limits in water using EPA Method 8270 with SIM (0.00005 mg/liter) slightly exceed the groundwater screening levels (0.00003 mg/liter) while the method detection limits (0.00002 mg/liter) are slightly below the screening values. At petroleum release sites where these chemicals are COI and groundwater analytical results for these chemicals are reported either as estimated values (between the quantitation and detection limits) or below the detection limit the screening levels will be assumed to have been achieved. Additional support for this determination is provided if all other PAH chemicals are also reported at concentrations below screening levels.

The most commonly used analytical method for EDB in soils (EPA Method 8260) has typical quantitation (0.001 mg/kg) and detection (0.0003 mg/kg) limits that exceed the soil screening level concentration (0.00014 mg/kg). The soil screening level for EDB is based on protection of groundwater. The groundwater quantitation limit for EDB is below groundwater screening level. Examination of Table 2 of the guidance shows that for EDB the soil quantitation limits are low enough to evaluate the other relevant pathways and routes of exposure, 0.27 mg/kg for direct contact and 0.001 mg/kg for vapor intrusion. At petroleum release sites where EDB is a COI and groundwater is potentially impacted and representative groundwater samples report EDB below the screening level but soil quantitation limits are above the soil screening level the groundwater results will take precedence.

In the screening level evaluation, the user must compare maximum media-specific concentrations measured during site assessment activities to the screening levels. If the measured concentrations do not exceed the screening levels, the site may be eligible for site closure. If the measured concentrations do exceed screening levels, the user may select screening levels as the remediation standards upon which corrective action is based and develop a CAP. The user may also choose to conduct additional investigation or evaluation and perform a site-specific risk evaluation. Samples may also have results reported as undetected at a concentration that is less than the PQL but higher than the screening level. In this case, a potentially unacceptable risk would be indicated.

2) Site-Specific Risk Evaluation
During the site-specific risk evaluation process, media-specific chemical concentration data are collected and used, along with assumptions regarding exposure pathways and receptors, to calculate risk to expected receptors. If the calculated risk is unacceptable, media-specific, risk-based chemical concentrations are established. These risk-based concentrations become the remediation standards for site corrective action. Samples are then taken during and after corrective action to demonstrate the standards have been attained.

PQLs for selected analytes in a given media sample may exceed one or more of the calculated risk-based remediation standards, making the demonstration that the standard has been attained problematic. It is also problematic when samples with results below a PQL are included in the calculation of exposure point concentrations and risk.

Remediation standards are oftentimes the lowest at sites where:

- screening levels have been selected as the standards,
- unrestricted use is the desired corrective action land use goal,
- contamination has migrated offsite in groundwater,
- on-site vapor intrusion risk is determined to exist, or
- diesel fuel contamination (and polynuclear aromatic hydrocarbon chemicals) is present in surface soil or in close proximity to surface water.

Accordingly, PQL-related issues often arise at such sites.

Table 1. Method detection limit (MDL) and practical quantitation limit (PQL) soil, water, and vapor concentrations for petroleum chemicals of interest using selected analytical methods

Checklist for Proposals to Use PQLs as Remediation Standards

Proposals to DEQ for the use of PQLs as remediation standards at petroleum release sites should include:

- the results of any risk evaluation,
- the remediation standards developed from that process,
- the proposed PQL, and
- the site-specific issues, with supporting information, that justify the use of the proposed PQL(s) as a remediation standard(s).

The supporting information that should be provided in the proposal is listed below along with a discussion of how DEQ will evaluate that information along with potential solutions to various issues, as they may be relevant to the site being evaluated, Given the number and variety of factors which may arise regarding PQLs in relation to remediation standards both the list and the discussion are not considered all-inclusive.

1. Risk Evaluation

- Describe the conceptual site model.
- Identify the level of risk evaluation, the chemicals, media, and pathway or route of exposure that are at issue.
- State the magnitude of the proposed PQL and MDL vs. the remediation standard.

Screening Level Evaluation

For sites where a screening level evaluation has taken place and the proposal is to use PQLs in place of screening levels as remediation standards for specific COI and media, the information provided will be reviewed in a number of ways. The proposed PQLs will first be reviewed relative to the conceptual site model and the pathway/routes of exposure, which are the basis of the screening levels for the chemicals under consideration.

- If the PQL for a chemical exceeds a soil screening level based on groundwater protection but the PQL achieves the groundwater screening level (also based on groundwater protection) for the same chemical, the soil PQL may be used as the soil remediation standard for that chemical.
- If the PQL for a chemical exceeds a soil or groundwater screening level for other routes of exposure (groundwater ingestion, vapor inhalation, or direct contact), DEQ will review the magnitude of the difference between the PQL/MDL and the screening level (whether greater than or less than the screening level) for all COI with a common route of exposure to estimate the potential impact on the cumulative risk from that pathway.
- If the pathway or route of exposure for the media-specific screening level for that chemical can be considered incomplete and the PQL is below the

screening levels for any other complete/potentially complete pathways/routes of exposure for that chemical and media the PQL may be acceptable as a remediation standard. DEQ will use Table 2 of this guidance for evaluation. Alternatively, the screening level for the most appropriate pathway or route of exposure may be considered as a remediation standard.

If only a screening level evaluation has been done completion of a site-specific evaluation may revise the remediation standards and still allow unrestricted use of the site, if that is the desired/expected future land use condition.

Site-Specific Evaluation

PQL issues may be related to cleanup criteria from a site specific risk evaluation. Site specific evaluations depend on the calculation of cumulative risk to a receptor from all pathways/routes of exposure and chemicals, based on estimated exposure point concentrations. The calculation of exposure point concentrations can be influenced by the number of chemicals with PQL issues, proportion of samples with <PQL values, the magnitude of the PQL, and how these censored data are treated in the calculation procedure. If the calculations result in unacceptable risks cleanup levels for individual COI are calculated, some of which may be low enough to be exceeded by PQLs. DEQ will evaluate whether and to what extent < PQL data were used appropriately in these calculations, if the resultant calculated risks are over or under estimated, the degree to which the < PQL data contribute to overall risk, and whether the calculated cleanup criteria can be modified to avoid the PQL issue or if use of a PQL will not materially affect the protectiveness of the cleanup.

The assumptions of the conceptual site model and risk evaluation will be reviewed to determine if the land use scenarios, receptors, and input parameter values are appropriate. For example, while an assumption of residential use may be appropriate all of the specific pathways and routes of exposure assumed to be complete may not be. Exclusion of an inappropriate pathway may eliminate the specific PQL concern. Alternatively, the pathways/routes of exposure may be appropriate but the receptor/land use scenario may not be.

If the PQL for a COI is above a remediation standard but the MDL is at or below the standard there may be instances where sample results falling between these limits can be considered to have met the remediation standard. If a sample result is reported as an estimated value and that concentration is at or below the remediation standard the standard will have been met, Sample results reported as undetected (less than the detection limit, provided the limit is at or below the standard) will have met the standard.

Additional guidance on the treatment of PQL/MDL data and issues in site-specific risk evaluation are available in the EPA *Guidance for Data Useability in Risk Assessment (Part A)* (EPA 1992), the *Risk Assessment Guidance for Superfund*,

Volume I, Part A (EPA 1989), and the EPA ProUCL statistical software technical guide (EPA 2010).

2. Analytical Issues

- Identify the analytical methods used that are the basis of the PQL
- Provide all relevant QA/QC information from the laboratory sheets for the analyses in question including data quality assessment and summaries provided by the laboratory.

When reviewing the proposal DEQ will evaluate whether the data quality assessment and QA/QC accompanying the analytical results adequately explain and support the PQLs proposed. Generally, PQL proposals should be based on PQLs derived from undiluted samples. Elevated PQLs resulting from sample dilution are typically the result of an attempt to quantitate all the COI when the concentrations of one or more chemicals (some of which may not be COI) are highly elevated, often referred to as matrix interference.

Matrix interference can also occur due to the nature of the media (soils in particular) which can impair the quantitation of a COI. The matrix spike and matrix spike duplicate portions of the laboratory QA procedures can sometimes clarify whether there are matrix interferences and whether they are causing over or underestimation of actual concentrations of a COI.

3. Sampling

- Provide information on the number of sampling events completed to support the PQL proposal.
- Provide information on the sampling procedures and QA/QC measures implemented during each of the sampling programs undertaken at the release site. Copies of quality assurance project plans and evaluations of adherence to and departure from those plans for the site in question for each event should be included.

The owner/operator may select alternative sampling procedures, which may provide for a lower PQL. The PQLs for analysis of air and vapor samples can be dramatically affected by the volume of air which is sampled.

DEQ will review the proposal for use of a specific PQL as a remediation standard as part of the overall CAP and approve or deny the request along with specifying any conditions of approval or reasons for denial.

THE INFORMATIONAL TEXT CONTAINED ON THE NEXT FEW PAGES (UP TO "SECTION 1 – TITLE AND APPROVAL PAGE") IS INTENDED FOR USE BY STAFF TASKED WITH GENERATING A NEW PROJECT QAPP, AND SHOULD BE DELETED FROM THE DOCUMENT PRIOR TO FINALIZATION.

Example/Template QAPP – Rev 1.2 – 01/13/2012

The following few pages contain important information and general instructions for all Department of Environmental Quality (DEQ) personnel assigned the task of generating, reviewing, or approving a DEQ Quality Assurance Project Plan (QAPP). A thorough understanding of these instructions will expedite the QAPP development process, and all personnel involved in these tasks are highly encouraged to read these pages prior to initiating the process. Before submission of the QAPP for approval, these four pages of instructional notes should be deleted, including this page and all the following pages up to Section 1 – "Title and Approval Page".

All DEQ staff involved in generating a project QAPP are also strongly encouraged to read the current revision of the DEQ Quality Management Plan (QMP), and the "EPA Guidance for Quality Assurance Project Plans, EPA QA/G-5" document, which explains each section of a project QAPP in more detail. These two documents can be accessed via hyperlinks located on the Inside DEQ Intranet "Quality Assurance" page, and on the last page of these instructions.

This document is intended to be both an example QAPP, and a template for use, by those who need to author a DEQ project QAPP. The format of this document is designed to comply with the DEQ Quality Management Plan, and to meet the minimum quality system requirements as established by the EPA. Previous versions of the DEQ QAPP outline should no longer be used.

In order to ensure progressive QAPP document improvement across the agency, the latest version of this example/template QAPP should be obtained from the DEQ intranet each time that a new project QAPP is to be developed. Through the incorporation of feedback and input from project personnel, this example/template QAPP will continue to improve over time.

The text in this document, which is highlighted in grey, is considered example language which must be revised and edited as necessary to reflect the needs of the actual individual project for which the new QAPP is being written. Text in this document that is NOT highlighted in grey is considered language that is critical to meeting the minimum intent of the DEQ QMP. Much of this non-highlighted language is expected to be applicable to most DEQ QAPP's. If the non-highlighted text is edited to satisfy specific project requirements, the revision must address the intent of the original text in an equivalent or superior fashion.

The format (Sections 1 through 25) of this document shall not be changed, as it is specifically designed to comply with the DEQ QMP, and to meet current EPA requirements. Please also note that all sections in the included outline must be filled out, leaving no blank sections. If a section is not applicable to the project, an explanation of why that section is not relevant is required.

REC 4853

TR 1538

Through the use of this example/template QAPP, rather than a blank template, the individual project author will have the opportunity to use portions of the existing language that are applicable to their project. This example/template document is based on a Nitrate Priority Area QAPP, originally authored by the Boise Regional Office, and further enhanced by the Idaho Falls Regional Office. The example language serves to illustrate the level of detail necessary for a typical DEQ project QAPP.

Use of this example/template QAPP is intended to make the process of creating a new DEQ project QAPP simpler, more robust, and increasingly uniform throughout the agency. For additional guidance on what information should be included in each section of the example/template QAPP, please refer to the "EPA QA/G-5 Guidance for Quality Assurance Project Plans" document, which explains each section in more detail.

Please note that this example/template QAPP is not intended to be an "off-the-shelf" completed project QAPP. It is intended as an aid for QAPP development, and to help ensure a level of consistency across the agency. While it is not possible to develop an example QAPP that will satisfy the detailed needs of all projects which may arise in the performance of DEQ project work, the provided example language will guide project personnel in their efforts to produce an acceptable QAPP.

This example/template QAPP is also based upon the assumption that the project for which a QAPP is being developed uses a laboratory to analyze samples. Not all DEQ projects gather samples in the process of gathering project data. In cases where only data is gathered, some portions of the non-shaded language may not be applicable, and should be removed. However, please remember that no section can be left blank. If a section is not applicable to the project, an explanation of why that section is not relevant is necessary.

For projects requiring the use of existing data, DEQ QAPP authors should follow the steps outlined in Chapter 3 of the EPA "Guidance for Quality Assurance Project Plans" document (EPA QA/G-5).

As mentioned previously, this document will be revised on a regular basis, based on input from Regional and State Office staff. The DEQ will also be revising the entire DEQ Quality Management Plan (QMP), based on comments received from the EPA during the September 2011 Quality System Review (QSR) of the DEQ quality assurance program.

The DEQ QMP revision process will involve frequent consultation with the EPA, and will likely result in several changes to the current program. During this transitional period, the example/template QAPP may occasionally be revised to reflect the most significant changes made to the overall DEQ quality system.

Suggestions for improvement of this document, which meet EPA requirements, are highly encouraged. Please bring all suggestions to the attention of the DEQ Quality Assurance Director.

REC 4854

TR 1539

To help alleviate confusion with respect to the general roles of various project personnel, please refer to Table 2 of the example/template QAPP for an in-depth description of these roles and responsibilities.
The following links contain resources that will provide helpful information and guidance to all DEQ personnel tasked with generating a project QAPP. The first link provided below will bring the user to the "Quality Assurance" area of the "Inside DEQ" Intranet Page.

For DEQ personnel tasked with writing a project Quality Assurance Project Plan, the **EPA QA/G-5 Guidance document** provides clear and detailed explanations on how to fill out the required sections. This example/template QAPP only provides the framework for a project QAPP, the bulk of the information must be supplied by the author of the QAPP. The EPA QA/G-5 guidance document will be of significant assistance to the QAPP author, and use of that document (see link below) is highly recommended.

Link to the DEQ intranet page which provides several links to the major EPA and DEQ QA System documents:
http://insidedeq.deq-intra/director/quality.htm

Link to the "DEQ Quality Management Plan" (QMP):
This document describes the overall quality assurance system used by the DEQ. It provides the general description of how the DEQ quality assurance system functions, what the elements of the system are, and basic requirements for DEQ quality system documents.
http://insidedeq.deq-intra/director/quality/quality_mgmt_plan_07.pdf

Link to the EPA "Guidance for Quality Assurance Project Plans" (EPA QA/G-5) document:
In conjunction with the DEQ QMP, this document provides detailed guidance to project personnel with respect to how to write a project QAPP.
http://www.epa.gov/quality/qs-docs/g5-final.pdf

Link to the EPA page listing several resources related to writing a project QAPP:
http://www.epa.gov/quality/qapps.html

2. Table of Contents

The Table of Contents (Below) must be updated following the completion of the new QAPP.

This can easily be accomplished using Microsoft Word, through use of the following steps:

1. After the draft project QAPP has been completed, open the document in Microsoft Word 2010
2. Print this page so that you have these directions (if needed), then delete these shaded "table of contents directions" so that they will not be included in your newly created table of contents.
3. Using the mouse, single left click the table of contents, which will turn the table grey.
4. After a few seconds, a tab with the words "Update Table" on it will open at the top of the table of contents.
5. Click on the "Update Table" tab, and then select the "Update Entire Table" option.
6. Click "OK", and the table of contents will immediately update.
7. Click anywhere in the document, outside the table of contents, and the table of contents update procedure will be completed.

4. PROJECT/TASK ORGANIZATION

Table 2: Key project personnel and associated responsibilities.

Name	Project Title/Responsibility
Name of assigned DEQ Staff	**Program Manager:** This person is the regional manager or state office program manager who will assist in the development, review, and approval of the project QAPP. Responsible for ensuring that the project QAPP is designed to meet the data needs of the program, and references current approved program procedures and policies. The Program Manager will also select a qualified Project Quality Assurance Officer, and after obtaining approval for this selection from the DEQ Quality Assurance Director, assign this individual to the project. This process is designed to enhance impartiality, and to ensure the accuracy of the authorized Project QA Officer list maintained by the DEQ Quality Assurance Director.
Name of assigned DEQ Staff	**Project Quality Assurance Officer**: Each project is to have an assigned Project QA Officer (QAO). This person will assist in the development, review, and approval of the project QAPP, and project related documents such as Field Sampling Plans (FSPs). The Project QAO will perform periodic project reviews/audits in accordance with the DEQ QMP, and provide data verification and validation per the project QAPP and FSP. The Project QA Officer may also be part of the review team for project final reports. In matters of project quality assurance, this individual will have a direct line of communication to the DEQ Quality Assurance Director. Per EPA requirements, the Project QA Officer shall review the QAPP annually, to determine if revision is necessary. The Project QA Officer shall not be the Project Technical Lead, the Project Manager, the Program Manager, or be otherwise assigned to the project data generation efforts. Neither the Project Manager nor the Project Quality Assurance Officer may directly report to the other within the DEQ organizational structure, and both of these individuals may not be directly supervised by the same person. All assigned Project QA Officers shall, prior to signing for the approval of any project QAPP, contact the DEQ Quality Assurance Director to discuss the project. At that time, the DEQ QA Director shall also verify that the assigned Project QA Officer is on the authorized Project QA Officer list. This process is designed to ensure that all DEQ QAPPs are approved, and issued, in accordance with the DEQ Quality Management Plan.

REC 4862

TR 1547

Name	Project Title/Responsibility
Name of assigned DEQ Staff	**Project Manager:** This person is responsible for overall project planning, document development and approval, sample planning and coordination, laboratory coordination, data review and verification, reporting functions, project report/summary development, and documentation of all project activities in the TRIM system and elsewhere as required by the project documents. Responsible for ensuring all project work is conducted in accordance with the DEQ QMP, and the approved project QAPP and associated FSPs. The Project Manager is responsible for ensuring that personnel assigned to this project are appropriately trained and qualified, with the corresponding training records on file in Human Resources. This individual will also perform periodic project reviews/audits in accordance with the DEQ QMP, and provide data verification and validation per the project QAPP and associated FSPs. The Project Manager may also be part of the review team for project final reports. The Project Manager shall review the project QAPP annually, and determine if revision is necessary. If the QAPP does require revision, the revised QAPP must be submitted for approval prior to implementation, per the DEQ QMP.
Name of assigned DEQ Staff	**Project Technical Lead**: This individual is to be familiar with the technical aspects of the project, and is assigned by the Program / Project Manager to be the technical lead and to assist in the development of the project specific QAPP. This individual should have experience in the methods, procedures, and equipment to be employed in the conduct of the work described in the QAPP. Also responsible for Coordination with sample location contacts, management of day-to-day aspects of sampling; planning, data collection, sample handling, coordination with the labs for sample shipping and analysis, receipt of resulting data, and data review and verification per the approved project QAPP and associated FSPs. This individual should be familiar with the information contained in the EPA Guidance for Quality Assurance Project Plans, EPA QA/G-5 document.
Name of assigned DEQ Staff	**Laboratory Contact/Manager**: Laboratory sample receipt, analysis, and laboratory data review.

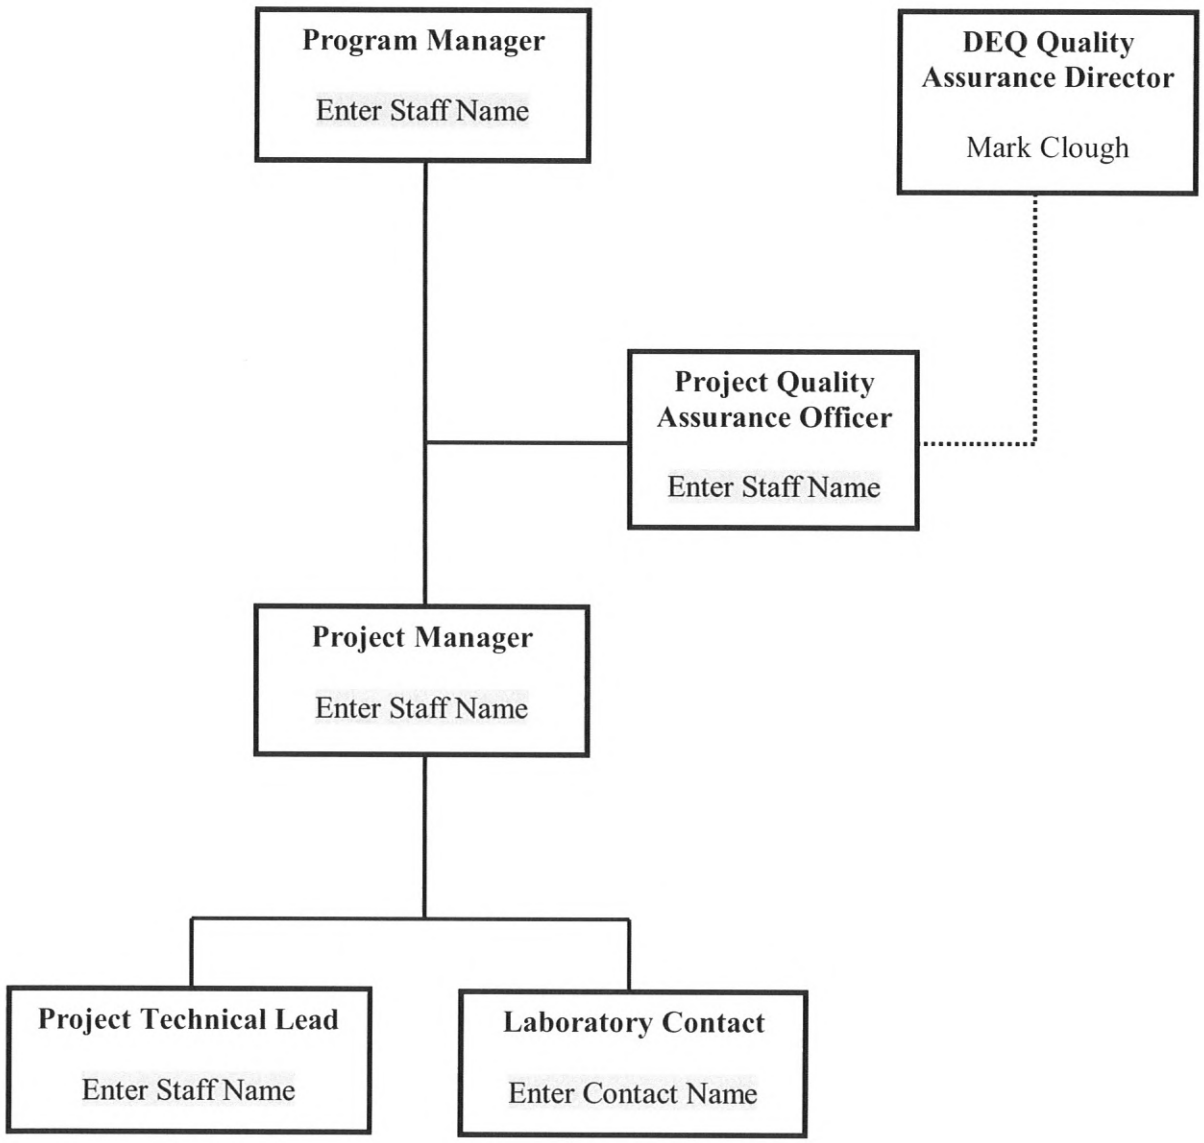

Figure 1: Project organizational chart

REC 4864

TR 1549

5. PROBLEM DEFINITION/BACKGROUND

A. Problem Statement

The Idaho Department of Environmental Quality (DEQ) is responsible for conducting regional ground water monitoring activities, per the Idaho Ground Water Quality Plan. The DEQ Idaho Falls Regional Office (IFRO) develops monitoring projects to investigate regional ground water quality issues. These issues can be the result of local public concern, regional office priority, or State-wide Departmental emphasis. Regional projects may include nitrate source or trend-related investigations focusing on Nitrate Priority Areas (NPAs), and sampling to address specific local concerns such as arsenic. The DEQ regional office is also charged with facilitating drinking water source protection. Projects may include sampling to support protection implementation strategies.

The overall rational for regional nitrate monitoring activities is to address DEQ's responsibilities under the Ground Water Quality Plan, summed up as to provide ground water monitoring data that will aid in:

- identifying areas of high vulnerability
- assess concentration trends in areas of degraded ground water quality
- identify, delineate, and explain sources of variability and degradation at regional and local levels,
- informing, directing, and prioritizing ground water protection programs and efforts, and
- Providing a means of evaluating effectiveness of best management practices, improving these best management practices, and to support regulatory decisions.

This Quality Assurance Project Plan (QAPP) provides a framework for data collection to identify potential sources of impact to ground water within the region. More specifically, this QAPP includes elements consistent for ground water monitoring events focusing on identifying potential sources of nitrate impacts to drinking water sources, primarily ground water. Nitrate-related sampling campaigns shall reference this QAPP, and include a Field Sampling Plan (FSP) detailing specific objectives, analytes, sampling strategies, pertinent background and sample locations.

REC 4865

TR 1550

B. Intended Usage of Data

The data collected for the Regional NPA Monitoring will be used to determine the nature and extent of ground water contamination due to nitrate. The sample results will be shared with Idaho State Department of Agriculture (ISDA) or other agencies, as necessary, to determine appropriate response activities. All sample results will be entered into the DEQ Ground Water Quality Database and be available through the online mapping application.

Sample results for NPA monitoring will be presented in either an annual DEQ ground water monitoring report or a campaign/project-specific report that will be included in the DEQ Ground Water Technical Report Series. Nitrate data may also be used in the NPA ranking process.

Private well owners will receive a report of analytical data from samples collected from their well. Appropriate data interpretation and recommendations may also be included.

6. PROJECT/TASK DESCRIPTION

A. General Overview of Project

Sampling projects will assess regional and local ground water quality impacts to the public due to the nitrates in ground water. The framework for monitoring to assess regional and local water quality and impacts will be described in a regional nitrate monitoring design document to be developed. A project/campaign-specific description, including network design/site selection will be included in the FSP for each monitoring campaign. Sites will be selected based on a combination of criteria, as pertinent to the specific project, including; well completion depth, location, accessibility, and historic sample results. Random or stratified random selection processes may be employed. Preference may be given to wells representative of sensitive populations and wells screened in the upper-most aquifer or portion of the aquifer. Priority may also be given to previously sampled wells to allow development/evaluation of trends.

Samples may be collected at each location for analysis of one or more of the following, as required for the specific sampling campaign:

- Major cations (e.g. calcium, magnesium, sodium, potassium)
- anions (e.g., nitrate, nitrite, sulfate, chloride, bromide, fluoride and o-phosphate)
- ammonia
- bacteria: total coliform bacteria , E. coli

REC 4866

TR 1551

- nitrogen isotope ($\delta^{15}N$)
- oxygen/deuterium isotopic ($\delta^{2}H$- $\delta^{18}O$)
- nitrogen and oxygen isotopic for nitrate anion ($\delta^{15}N_{NO3}$, $\delta^{18}O_{NO3}$)
- tritium
- Pharmaceuticals and Personal Care Products (PPCPs)

Sample submission may follow a staged approach to maximize cost vs. diagnostic benefits; for example while samples collected for less costly analyses such as $\delta^{15}N$, and $\delta^{18}O$ may be collected and submitted for all sites, samples for more expensive analyses such as $\delta^{15}N_{NO3}$ and $\delta^{18}O_{NO3}$ or PPCPs may be collected at all sites, but not submitted for analysis unless initial results indicate that such information may confirm contamination sources or geochemical processes are occurring. These tiered analyses may aid in correctly identifying the primary factors to explain contaminant conditions observed. Holding times and sample preservation requirements would allow for this staged approach.

B. Project Timetable

The specific project timetable will be designated for each monitoring project in the FSP.

7. QUALITY OBJECTIVES AND CRITERIA

The objective of quality assurance and quality control (QA/QC) is to assure that analytical results obtained by sample analyses are representative of actual chemical and physical compositions of the ground water. Field QA/QC will consist of following a standard protocol for sample collection and by collecting and analyzing sample duplicates and field blanks. The duplicates will be used to determine both field and laboratory precision. The field blank will be used to check the integrity of the sample collection and handling process. Both the duplicate and field blank samples are stored and handled with the normal sample load for shipment to the laboratory. Project goals and sampling conditions may require additional field QC samples, including equipment blanks or spiked samples. Field QC samples will be submitted "blind". Ideally, at least one set of field quality assurance samples will accompany each sample shipment or analysis batch.

Field QC samples will comprise at least 10% of all samples with a goal of 20% QC samples.

Field screening data (e.g., field parameters of pH, temperature, specific conductivity, and dissolved oxygen) are at data quality Level I (field parameter/ screening level data). Laboratory analytical data (i.e., data from samples submitted to a laboratory for analysis) are at data quality Level III (standard laboratory procedures and data reviewed by standard Quality Assurance protocols). Specific data quality objectives or requirements will be included in the FSP if not included in the project QAPP.

A. Data Precision, Accuracy, Measurement Range

Accuracy is a measure of the closeness of the agreement between a "true" or reference value and the associated measured value. A sampling campaign may include spiked samples with a known matrix submitted blind to the laboratory or may rely on reported recoveries for Laboratory Control Samples (LCS). The recoveries of laboratory control samples (LCS), matrix spikes, and surrogate spikes will be used to evaluate the accuracy of the measurements. These recoveries are typically calculated as "percent recovery" represented by the following equations:

Spiked sample or LCS Percent Recovery:

$$\%R = C_M / C_T * 100$$

Where: C_M = Measured spike/LCS concentration
C_T = True spike/LCS concentration

Matrix Spike and Surrogate Recoveries:

$$\%R = (C_S - C_{US}) / C_T * 100$$

Where : C_S = Measured concentration of Spiked Sample
C_{US} = Measured concentration of Un-Spiked Sample
C_T = True Concentration of Spike Added

Laboratory accuracy for each analysis is set by a statistical analysis of the laboratory equipment and the acceptable accuracy range for the laboratory equipment will be indicated in the laboratory sheets. Any outliers from the acceptable range in % Recovery, as determined by the laboratory, will be flagged by the laboratory. Typical accuracy goals will be ± 20%. Accuracy goals will be specified in the FSP if not specified in the QAPP.

Precision is a measure of agreement between two measurements of the same property under prescribed conditions. Sampling campaigns may include duplicate samples (field replicates or split samples) or may rely on LCS split sample results. The Relative Percent Difference (RPD) of duplicate samples will be used to assess data precision. For laboratory duplicates, field duplicates and matrix spike duplicates, the following equation will be used to calculate Relative Percent Difference (RPD):

$$RPD = \frac{(C_1 - C_2)}{(C_1 + C_2) / 2} * 100$$

Where: C_1 = Concentration in first sample
C_2 = Concentration in the second/duplicate sample
Where both C_1 and C_2 > 5 times the laboratory Method Detection Limit (MDL).
Where one or both C_1 and C_2 are less than 5 times the MDL, the results will be considered within control limits where C_1 and C_2 are ± MDL.

For radiological samples, such as tritium, precision will be assessed by RPD where both results exceed 5 times the MDL, otherwise results will be considered within control limits when within 3 times Pooled Standard Error (PSE):

$$PSE = /R_1-R_2/ \leq 3(S_1^2 + S_2^2)^{1/2}$$

Where:

R_1 = concentration in first sample
R_2 = concentration in second/duplicate sample
S_1 = analytical uncertainty (counting error associated with laboratory measurement of the first sample)
S_2 = analytical uncertainty (counting error associated with laboratory measurement of the duplicate sample)

The goal for precision and what that precision will be based on for each sampling campaign will be included in the FSP if not included in the QAPP. In general, precision will be based on field duplicates with a goal of ± 20%.

Appropriate **Measurement Range** is determined by reviewing results with comparison to the laboratory reporting levels/MDL. Reporting requirements are determined prior to sampling through review of historical data for the analytes and region of interest, and reflected in choice of analytical laboratories, analysis methods and requested reporting levels/MDL. Assessment criteria and goals will be described in the FSP if not included in the QAPP.

B. Data Representativeness

Representativeness is defined as the degree to which the sample data accurately and precisely represent site conditions. The representativeness criterion is best satisfied by confirming that sampling locations are properly selected, sample collection procedures are appropriate and consistently followed, a sufficient number of samples are collected, and analytical results meet data quality objectives. All sampling procedures will follow the sampling procedures in the sampling protocol in Appendix A. Representativeness is evaluated by comparing the combination of data accuracy, precision, appropriate measurement range and methods, and assessing other potential sources of bias; including sample holding times, blank samples, and laboratory quality assurance review. Any additional specific assessment criteria and goals will be described in the FSP if not included in the QAPP.

C. Data Comparability

Comparability is defined as the confidence with which one data set can be compared to another data set. Using standard sampling and analytical procedures will maximize

comparability. In an effort to ensure data comparability, sample collection protocols (included in Appendix A) will be consistently followed, the same analytical procedures will be used, and the same laboratory will be used to analyze the samples throughout each project. The FSP for each project will include the laboratory to be used for each analyte.

D. Data Completeness

Completeness is defined as the percentage of valid data relative to the total possible data points. For data to be considered valid, it must meet all of the acceptance criteria, including accuracy and precision, as well as any other criteria specified by the analytical method used. The overall data quality objective for completeness for the sampling events conducted under this QAPP is 80%. Any required departure from this goal will be justified and explained in the FSP.

8. SPECIAL TRAINING/CERTIFICATION

The Project Manager and/or Program Manager is responsible for ensuring that personnel assigned to this project are appropriately trained and qualified, with the appropriate training records on file in DEQ Human Resources.

All work performed by DEQ personnel will be conducted in accordance with the State of Idaho Worker Health and Safety Plan.

No special training for ground water sample collection is required; staff will have previous ground water sampling experience and on-the-job training.

9. DOCUMENTATION AND RECORDS

Project documents will be filed electronically in TRIM, in accordance with applicable program filing procedures. The Project Manager is responsible for ensuring that the most current approved revision of the project QAPP, with related FSPs and SOPs, is available in the DEQ TRIM electronic records management system.

Field personnel will document each day's activities in field notes. Information is to be recorded as follows:

- Project data must be recorded directly, promptly, and legibly.
- Field logbook or field sheet entries must be made in black or blue permanent ink and must be signed/initialed and dated by the person making the entry.
- Changes or corrections to data must be indicated with a single line through the original entry.
- Changes must be initialed, dated, and explained.

In addition to field notes (as identified in Appendix B at a minimum), documentation is to include all data used to develop the monitoring network, well sampling permission documentation, a sampling procedures document, the reports summarizing the sampling events and results.

10. SAMPLING PROCESS DESIGN

A. Rationale for Selection of Sampling Sites

The nitrate priority area monitoring network will consist of existing private domestic, irrigation or public water system wells that are selected following the protocol (to be developed) for the IFRO Regional Ground Water Monitoring Network Design. Sampling frequency, where not described in the regional ground water monitoring design document, will be described in the associated FSP. The specific FSP will identify the number of sample locations and specify analytes, collection and analysis requirements, special handling or follow-up criteria and reporting requirements. Permission from the well owner will be obtained prior to sampling each well.

B. Sample Design Logistics

Sampling logistics will be identified in the specific monitoring campaign FSP if not identified in this QAPP.

11. SAMPLING METHODS

QA/QC procedures as specified for sample collection will be followed by sampling personnel. The QA/QC procedures will be fulfilled by adhering to all requirements detailed in this QAPP and the ground water sampling procedure located in Appendix A of this QAPP. Such adherence will be demonstrated through appropriate documentation of sampling procedures within the field logbook or field sheets as described herein. Field audits by the Project QA Officer may also be part of QA/QC procedures.

Samples collected from private domestic wells, irrigation or public supply wells will utilize the existing pump and distribution system. Water samples will be collected from a faucet or sample port nearest the well and before any treatment system. Samples collected from monitoring wells will utilize a submersible pump, peristaltic pump, or disposable bailer. If a pump is used, dedicated or disposable tubing will also be used. Equipment blanks may be included with the complement of quality assurance samples.

A portable meter will be used to measure pH, specific conductance, dissolved oxygen, and temperature at each sample location. A GPS will be used to determine the longitude and latitude of the well/sampling point.

Field work quality will be controlled by following standard sampling protocols (Appendix A) during each sampling event, using consistent sampling containers and laboratories, and collecting sample duplicates and blanks. Protocols for items such as equipment decontamination, chain of custody forms, sample blanks, etc, are found in Appendix A, and further detailed in the project FSP. Detailed field notes will be taken for quality control and proper sample identification.

Analytes, laboratories, shipping addresses, and current contract numbers as appropriate are included in Table 3. Analytical methods, sample container, preservation and holding times are identified in Section 13 and Table 4.

Table 3: Analytes, laboratories, and contract numbers.

Analytes	**Preferred analyzing Laboratory**	**Shipping address**	**DEQ Contract number**
Major anions, Major cations, nutrients	State of Idaho Bureau of Laboratories	2220 Old Penitentiary Rd Boise ID 83712	MOA
Bacteria: Total Coliforms, E. Coli	IAS-EnviroChem	3314 Pole Line Road Pocatello, ID 83201	Vendor

Analytes	Preferred analyzing Laboratory	Shipping address	DEQ Contract number
Pharmaceuticals and Personal Care Products (PPCPs)	(Appropriate Laboratories and contacts will be developed as needed)	(Update)	(Update)

12. SAMPLE HANDLING AND CUSTODY

Samples will be collected by DEQ personnel into laboratory-supplied sampling containers, labeled, placed in an ice-chilled cooler and transported directly to the laboratory or shipment location. Samples collected for $^{15}N_{NO3}$ and $^{18}O_{NO3}$ analysis will be frozen at DEQ until the chemistry and other stable isotope results from the sample location are received and reviewed.

Where analytical results for a sample location exceed 5 mg/L, and/or supporting results suggest chemical evolution of nitrogen in groundwater samples collected for $^{15}N_{NO3}$ and $^{18}O_{NO3}$ analysis may be sent to University of Waterloo EIL or Northern Arizona University CPSIL for analysis. DEQ personnel will oversee proper storage and handling of all samples collected until transferred into the care of others. Properly filled out chain of custody forms will be used and maintained at all times. Protocols for chain of custody forms, sample handling, etc, are found in Appendix A, and further detailed in the project FSP. Chain of custody forms will accompany the samples from the time of sample collection throughout the duration of the shipping process.

13. ANALYTICAL METHODS

All sample containers, labels, and preservatives will be obtained from the analytical laboratory. Samples must be preserved and analyzed within the holding times. The laboratory will be notified prior to sample shipment to ensure the holding time is not exceeded. All other instructions provided by the analytical laboratory will be followed throughout the duration of each project.

Table 3 lists analytical laboratories for the NPA monitoring projects, including the potential parameters to be analyzed by that laboratory and the location of the laboratory. Samples may be sent to other laboratories as needed to achieve specific sample campaign objectives. In general, samples for major ion/common ion chemistry and nutrients will be sent to Idaho Bureau of Laboratories, Boise; bacteria to IAS-Envirochem, Pocatello; and environmental-level tritium to Idaho State University EML. Stable isotope analysis may be sent to one or more laboratories based on factors including proven quality of results, timeliness of result

receipt, cost, and convenience. Inter laboratory comparisons may be conducted to determine long-term laboratory choices. Initially, the University of Arizona Environmental Isotope Laboratory will be used for ^{15}N, ^{18}O, ^{2}H analysis. A selection of samples for $^{15}N_{NO3}$, $^{18}O_{NO3}$ will be sent to University of Waterloo EIL, with comparison samples sent to Northern Arizona University CPSIL for analysis and method comparison. Future analysis result comparisons for ^{15}N, ^{18}O, and ^{2}H may also be made between University of Arizona and Northern Arizona University.

14. QUALITY CONTROL

A. Field QC Checks

Field QC samples, typically duplicates and blanks, will be submitted blind (not identified as a QC sample) for analysis. The overall field QC frequency will be at least 10% of the sample load. Submission of QC samples will be scheduled to ensure that at least one QC sample set will be included with each batch of samples submitted to the laboratory. Field QC checks are to be as evenly distributed as project conditions allow between duplicates, blanks, and spikes.

Duplicates

Duplicate samples are two samples collected from the same location and representing the same sampling event and are carried through all assessment and analytical procedures in an identical manner. Duplicate can be "replicates" (samples taken one immediately after the other, separated only be the actual time required to fill the sample container), or "splits" (subsamples drawn from the same initial volume of matrix). The FSP will describe the method for obtaining duplicate samples. Field sampling procedures outlined in Appendix A will also be followed for each of the sampling events to ensure consistency in sample collection. All relevant information will be recorded for the duplicates in the field logbook or field sheet. The duplicates will allow assessment of repeatability and accuracy of the sampling procedures and will also be used to assist in assessment of any cross-contamination issues. Results from the field duplicate analysis will be presented in the analytical report.

Field and Equipment Blanks

A blank is a sample of known matrix where the specific constituents requested for analysis are known to not be present, or are present at concentrations less than the laboratory lower limit of detection.

Field blanks are samples of blank matrix, typically deionized water, prepared in the field under similar conditions, processed the same as and included for analysis as a regular sample. Field blanks are a quality control check to identify potential problems with the sample collection, handling and analysis process. Equipment blanks are blank sample matrix passed through or over non-dedicated sampling equipment to check the decontamination process between samples or sample sites.

Equipment blanks may be collected when sampling equipment requiring decontamination (portable pumps, sampling manifolds, ect.) are carried from well to well. Equipment

blanks when collected, will also be submitted blind for analysis and may be included in the overall 10% QC sample calculation.

Field spikes
Samples from a third party vendor that include a known concentration of analytes of concern may be submitted blind to the analyzing laboratory. These "spiked" samples may be included in the sample load to allow for an independent accuracy assessment or for inter laboratory comparisons. Due to the added cost of procuring or preparing field spike samples these may not be included with all sampling campaigns. Use of spiked samples will be described in the FSP.

B. Laboratory QC Checks

Laboratory quality control checks are routinely performed as part of the analysis process. Frequency and type of QC samples are often analysis method-dependent and include reagent blanks, matrix spikes, and internal laboratory splits. Analyzing laboratories will report any variance from QC control limits impacting quality of sample results and may report details of internal laboratory QC if requested. The analytical laboratory may provide appropriate sample containers, chain of custody forms, sample labels, and any necessary container seals. Laboratory QA/QC and data reports will be filed in TRIM following applicable filing protocols.

Quality control checks include internal checks for sampling analysis activities, duplicate samples and blanks. Quality Control procedures for the laboratories have been certified through the U.S. Environmental Protection Agency. The following list documents key components of the laboratory QA/QC program for this project.

Laboratory Blanks

A laboratory blank is a sample of an uncontaminated reference matrix. The laboratory blank is analyzed to evaluate the accuracy of the analysis.

Laboratory Quality Control Samples
Laboratory control samples (LCSs) are samples that contain a known concentration of analytes and are analyzed to assess the overall method performance. They undergo the same preparatory and determinative procedures as the project environmental samples and are the primary indicator of laboratory performance. LCS recoveries are used to measure accuracy. The relative percent difference (RPD) for duplicate LCS recoveries is used to measure precision.

Laboratory Duplicate Sample

A laboratory duplicate sample is a sample that is split by the laboratory into two separate and identical samples. The two samples are analyzed and a comparison of the results (RPD) is used to assess laboratory precision.

Matrix Spike and Matrix Spike Duplicate (MS/MSD) Samples
A matrix spike (MS) is a sample with known amount of the target analyte added to project matrix before analysis to assess possible matrix interferences on the analysis. Percent recoveries (%R) on MS samples should be compared to %R of LCS samples. A MS, matrix spike duplicate (MSD) pair can be used to assess precision.

C. Data Analysis QC Checks

The QC check data may be checked/reviewed for quality by the Project Technical Lead, the Project Manager, or the Project QA Officer at any time during the project, and must be checked once all of the data is collected. Corrective actions, as needed, will be documented in the event that control limits are exceeded. Data qualifiers will be assigned following appropriate data verification/validation procedures. Any qualifiers added will be defined in the project summary/technical report and will be consistent with appropriate EPA guidance, EPA QA/G-8.

15. INSTRUMENT/EQUIPMENT TESTING, INSPECTION, AND MAINTENANCE

Laboratory instrument/equipment testing, inspection, and maintenance are performed by and documented by the laboratory as required by or consistent with the State of Idaho laboratory certification process. Procedures and schedules for preventive maintenance of sampling equipment are the responsibility of the laboratory. Each instrument or item of laboratory equipment will be maintained periodically to ensure accuracy. These procedures and frequency of performance are designated in the individual instrument manuals.

Project field instrument/equipment testing, inspection, and maintenance will be performed in accordance with the individual instrument/equipment manual.

16. INSTRUMENT/EQUIPMENT CALIBRATION AND FREQUENCY

Laboratory instrument calibration is conducted, and documented by the laboratories laboratory as required by or consistent with the State of Idaho certification process.

All field monitoring equipment for the measurement of field parameters (temperature, pH, specific conductance, dissolved oxygen) will be calibrated and maintained as recommended by the manufacturer, or as found in individual instrument/equipment manuals, to ensure accuracy within specified limits. Field equipment used to collect samples will be calibrated according to manufacturers' procedures or internal guidelines at the start of each field day (at a minimum) and/or at intervals recommended by the manufacturer or found in individual instrument/equipment manuals. Calibration details will be recorded in the field logbook or field sheet.

17. INSPECTION/ACCEPTANCE OF SUPPLIES AND CONSUMABLES

The equipment and supplies required for monitoring campaigns will be consistent with the included ground water sampling procedure (Appendix A). Sampling equipment and personal protective equipment beyond that listed in the ground water sampling procedure will be documented in the FSP (i.e. if antibiotics or steroids are collected, a face mask will be used). All sample containers may be obtained from the analytical laboratory. All gloves, face masks, and sample containers will be new, and will be used once during each sample collection. Each instrument or item will be calibrated per the individual instrument/equipment manuals, and also visually inspected by field sampling personnel for damage and operability.

18. NON-DIRECT MEASUREMENTS & DATA ACQUISITION

This section addresses data obtained from existing data sources, not directly measured or generated in the scope of this project.

The laboratories shall provide DEQ with a data package that includes the analytical results of the submitted samples, the QA/QC report for the analyses, and a copy of the chain-of-custody record. Laboratories may be requested to provide results and reports in an electronic format.

No other non-direct data is expected to be acquired.

19. DATA MANAGEMENT

Hard copies of field notes and laboratory data reports will be kept at least until data review and reporting is complete. Electronic copies of all field notes and laboratory reports will be kept in TRIM. The analytical results will be uploaded to the DEQ Ground Water Quality

database after review by the Project QA officer and will be available to the public through the DEQ online mapping application.

20. ASSESSMENT AND RESPONSE ACTIONS

Assessment of the project quality control plan will be performed by reviewing field notes and laboratory reports and by conducting field audits where possible. This assessment will be completed or directed by the Project QA Officer. Any errors or inconsistencies identified in the field notes will be investigated and corrected to ensure the integrity of the data and conformation to the QAPP and FSP. Review of internal laboratory quality assurance, audits, and surveillances or other types of laboratory assessments will also be taken into account. If unexpected analytical results are reported for any reason, the laboratory will be contacted to perform an additional quality review of the data in question. The Project QA Officer will perform additional assessment of the plan independently of the Project Manager and sampling lead.

A note to the file will be included with the field notes and laboratory reports if any follow up quality assurance activities regarding field notes or laboratory reports are conducted.

The Project QA Officer shall review the QAPP annually, to determine if revision is necessary. The Project Manager should also review the project QAPP on an annual basis to ensure that the project QAPP continues to meet the needs of the data users. If the project QAPP does require revision, the revised QAPP must be submitted for approval, prior to implementation, per the DEQ QMP.

21. REPORTS TO MANAGEMENT

Sample results for NPA-related monitoring will be presented in either an annual DEQ ground water monitoring report or a site-specific report that will be included in the DEQ Ground Water Technical Report Series.

22. DATA REVIEW, VERIFICATION, AND VALIDATION

Data collected under this QAPP will be reviewed by the Project Manager, Project Technical Lead, and the Project QA Officer to ensure the data has been recorded, transmitted, and processed correctly. RPDs will be calculated for all field duplicates and the laboratory %R and RPDs will be reviewed. Review by the Project QA Officer shall include a minimum of 10 percent of all project data with a goal of 20 percent. This review will include verification/validation to the original laboratory data reports.

REC 4880

TR 1565

Data verification and validation efforts will be recorded in project documentation.

23. VERIFICATION AND VALIDATION METHODS

DEQ personnel performing data verification and validation are encouraged to review the EPA guidance on methods for this task, found in EPA Guidance on environmental Data Verification and Data Validation, EPA QA/G-8.

Data verification will be performed by the Project Manager and/or Project Technical Lead by reviewing all chain-of-custody sheets, surrogate recoveries, method blanks and LCS and MS sample/sample duplicates to assess %R and range of RPDs. The %R and RPDs will be compared to project goals as described in the QAPP and FSP and an assessment of completeness will be made.

Data validation will be performed by the Project Manager and/or Project Technical Lead, and the Project QA Officer, extending the data evaluation beyond method and procedural compliance, to determine the analytical quality of the data set. Assignment of data validation qualifiers will be completed by the Project Manager and/or Project Technical Lead consistent with appropriate EPA guidance. Validation by the Project QA Officer will include review of data qualifiers. The intent of data validation is to determine if the data are adequate to support the objectives of the project. Items to be considered include: Does the data meet the needs of the project, does the data meet the quality objectives of the project, and are the conclusions drawn from the gathered data supportable. Data validation will also include a determination, where possible of the reasons for any failure to meet method, procedural, or contractual requirements, and an evaluation of the impact of such failure on the overall data set.

Any discrepancies from requirements of the QAPP, with respect to the data, will be noted during the verification and validation process. As determined by the Project Manager, the Project Technical Lead, or the Project QA Officer, if the data do not meet the needs of the project, or the quality objectives of the QAPP, and/or if the conclusions drawn from the data do not appear to be reasonable, the Project Manager and the Project QA Officer shall immediately report such findings to the appropriate Regional Manager and State Office Program Manager for determination of the necessary corrective actions.

24. RECONCILIATION WITH USER REQUIREMENTS

Data quality objectives (DQOs) will be discussed with the analytical laboratory as needed by the Project Manager or Project Technical Lead when DQOs are not met to insure that the laboratory is taking appropriate corrective action. Corrective actions may be initiated to suggest updates to internal laboratory QA procedures in order to rectify QA issues. If no

corrective actions are being implemented and no plan can be developed to address QA issues, the Project Manager will consider changing laboratories for future sampling events.

Data Quality Assessment (DQA) will be performed in accordance with the DEQ QMP. Additional guidance can also be found in EPA Data Quality Assessment: A Reviewer's Guide, EPA QA/G-9R, or in EPA, 2006, Data Quality Assessment: Statistical Methods for Practitioners, EPA QA/G-9S, EPA/240/B-06/003.

The DQA, performed by the Project Manager and the Project QA Officer, addresses the determination of if a data set is of the right type, quality, and quantity to achieve the objectives of the project and can confidently be used to make an informed decision.

As previously stated in Section 23, if the Project Manager, the Project Technical Lead, or the Project QA Officer, reach the conclusion that the project data do not meet the needs of the project, or the quality objectives of the QAPP, and/or if the conclusions drawn from the data do not appear to be reasonable, the Project Manager and the Project QA Officer shall immediately report such findings to the appropriate Regional Manager and State Office Program Manager for determination of the necessary corrective actions

If sampling activities require revision, the project QAPP and/or the project FSP will be revised as necessary. Following revision, and prior to implementation, the revised project QAPP and/or FSP must be re-approved in accordance with the Idaho DEQ QMP.

APPENDIX A - GROUND WATER SAMPLING PROCEDURES, IFRO SAMPLING PROJECTS

Note: In this example, a standard procedure for water sampling was incorporated into the project QAPP as an appendix. Not all project QAPP's will require this, but this example illustrates how this can be done. Another way to accomplish this is to reference an approved DEQ Standard Operating Procedure (SOP).

It must be noted and understood that this "Appendix A" is NOT the Field Sampling Plan (FSP) referenced in this example QAPP. A FSP is a stand-alone document that gives project specific information and direction with respect to project sampling. This example QAPP assumes that a FSP will be written to accompany the QAPP. If the project for which a QAPP is being written (using this example/template) will not have a specific FSP written for it, then all the information that this example/template QAPP defers to the FSP will need to be included within the new project QAPP itself.

Equipment required: field log book with collection data sheets, sample labels, water-proof pens and markers, cell phone, GPS, instruments for field parameter measurement, sample collection equipment (may include hose bib, sample collection port and associated tubing, peristaltic pump, bucket, submersible pump and generator), sample containers, preservatives, sample cooler and ice, powder-free nitrile or vinyl gloves, safety glasses or face shield, paper towels, first-aid equipment, bag for trash.

1.0 Well Purging Procedures

Each well/sample point will be purged until the field parameters stabilize as defined in Section 2 of this Appendix. The volume of water and amount of time required to properly purge each well will be dependent on the size and yielding characteristics of each well.

2.0 Field Parameter Measuring Procedures

Field measurements of pH, temperature, and specific conductance will be measured throughout the purging sequence and recorded on the field data sheet or logbook. Field parameters will be recorded at least once for every five minutes while the well is purged. Stabilization of these parameters is considered successful when three successive readings (a minimum of five minutes apart) meet the following criteria:

pH :	± 0.1 standard unit
Specific Conductance:	± 10µmhos/cm or ten percent of the preceding reading

Temperature: ± 0.5° C

Measurements of field parameters will be taken using a field parameter meter that is calibrated prior to each day of sampling. Water used in field parameter measurements will be collected into a dedicated bucket or flow-through from the sampling hose connected to a faucet nearest to the wellhead. All measurements collected will be recorded in the field sheets and field logbook with appropriate times and well identification information. When possible, static water level measurements will be recorded.

3.0 Sample Collection Procedures

Once the field parameters have stabilized, collect the sample from the faucet or sample port. If a hose must be used for sample collection, a dedicated hose supplied by DEQ will be used. Samples should be collected as quickly as possible following stabilization of the field parameters. Collect the sample directly into the appropriate container. If a filtered sample is required, use an in-line filter connected with tubing at the faucet or sample port. If the sample point or conditions do not allow use of an inline filter, a peristaltic pump can be used. Collect water from the sample point in a bucket that has been triple rinsed in the sample matrix. Purge the pump line by running at least 500 ml of the water through the pump and proceed to collect samples. Samplers will wear a new pair of vinyl/nitrile gloves at each location, and will keep gloves on until samples are collected and required preservatives added. Samples should be collected and handled in a way that reduces the potential for losing the analyte from the sample matrix; for a VOC samples, reduce the discharge to a low, laminar flow, leaving a positive meniscus but not allowing the container to overflow and thereby losing preservative from the container. Typically, sample containers that are not pre-preserved should be triple rinsed with the sample matrix prior to collection.

The samples will be labeled with durable labels and water-resistant ink to provide proper identification. Labels will have the following information: unique sample identification number, date and time of collection, parameters requested, and project name/number.

Preservation of the collected samples will follow laboratory instructions. Samples to be chilled will be placed on ice in an ice chest at less than 4° C from the time of sampling until the analysis is complete. All samples will be transported in ice chests with ice packs and chain of custody forms.

4.0 Decontamination Procedures

The sample collection equipment carried from one location to another will be rinsed with deionized water or sample matrix prior to collecting measurements at the new site. Equipment that cannot be sufficiently purged with the sample matrix prior to sample collection will be rinsed with deionized water. Decontamination between sites may

require a stronger solution, depending on the nature of the contaminant. Special decontamination procedures will be detailed in the FSP.

5.0 Field sampling sheets

Field sampling sheets within a bound logbook will be completed for each well at each site visit. An example field sample sheet is included in Appendix B. At a minimum, the following information, as available, will be documented for each site visited during each sampling event:

- Identification of the well
- Total well depth
- Approximate purge volume and rate
- Date and time of sample collection
- Sample identification numbers and parameters requested
- Field parameter measurements and methods
- Field observations and remarks
- Name of collectors
- Weather conditions

6.0 Chain of Custody Forms

Once the samples have been collected, they will be placed in an ice chest (with ice) while in the field, and stored in a designated sample refrigerator until delivered or shipped to the lab. A chain of custody form will accommodate each ice chest during shipment to the lab. The chain of custody form will include the following information:

- Project name/code
- Laboratory name and address
- Sample identification number
- Date and time of collection
- Type of sample, number of containers, and analysis requested
- Sample preservation methods
- Signature of sample collector(s)/shipper
- Date and time of release to shipper/common carrier

The following procedures will be followed to ensure proper chain of custody:

- The chain of custody record will be checked for a signature
- The sample will be stored in a secure area until it is analyzed.

7.0 Quality Assurance/Quality Control

REC 4887

TR 1572

The objective of quality assurance and quality control is to make certain that the ground water analytical results represent the actual chemical and physical composition of the ground water at the site. DEQ will be responsible for the QA/QC activities of the samples and analytical laboratories. Components of the QA/QC program are as follows:

Laboratory: The analytical laboratory will provide or assist in the sampling containers, preservatives, chain of custody, labels and seals. A laboratory QA/QC report with continuing calibration checks will accompany each data report and will be kept on file by DEQ.

Sample Collection: QA/QC procedures for sample collection will be accomplished by the sampling personnel. A standardized field logbook or field sheet will be kept for each sampling event following the format described above. It will include all label and seal numbers and documentation of QA/QC procedures related to sample collection.

Trip Blank: Trip blanks may be included if samples for VOA analysis are included with the project.

Field Blank: Field blanks will be collected at the rate of at least 5 percent.

Duplicate Samples: Duplicate samples will be collected at the rate of at least 5 percent.

Field Spike: Spikes prepared by an independent source and submitted blind to the lab may be included with field QC samples.

Field QC Sample Goals: Field QC samples (duplicates, blanks, and spikes) will constitute at least 10%-20% of samples submitted to the analyzing laboratory.

REC 4888

TR 1573

APPENDIX B - GROUND WATER SAMPLING FIELD SHEET - IFRO

In this example, this appendix was used to supply an approved field sheet to the staff engaged in sampling efforts. Not all project QAPP's will require this appendix, but this illustrates how this type of information is included in a QAPP.

This document has been reviewed in accordance with the U.S. Environmental Protection Agency's peer and administrative review policies and approved for presentation and publication. Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

REC 4896

TR 1581

PREFACE

The Office of Health and Environmental Assessment, in consultation with other Agency and non-Agency scientists, has prepared this health assessment to serve as a "source document" for Agency-wide use. Specifically, this document was prepared at the request of the Office of Air Quality Planning and Standards.

In the development of this assessment document, the scientific literature has been inventoried, key studies have been evaluated, and summary/conclusions have been prepared such that the toxicity of arsenic is qualitatively and, where possible, quantitatively identified. Observed effect levels and dose-response relationships are discussed where appropriate in order to place adverse health responses in perspective with observed environmental levels.

REC 4897

TR 1582

ABSTRACT

This document summarizes current scientific information regarding the effects of inorganic arsenic on man and the environment. The observed effects, as presented herein, constitute the health basis from which the U.S. Environmental Protection Agency will make determinations regarding regulatory initiatives pursuant to the Clean Air Act. Specifically, this document discusses the following topics--physical and chemical properties of inorganic arsenic; environmental distribution and cycling; inorganic arsenic metabolism; toxicology, including mutagenic and carcinogenic properties; and essentiality--and identifies the factors most germane to assessing quantitative and qualitative human health risks.

1. INTRODUCTION

This report evaluates health effects associated with arsenic exposure, with particular emphasis placed on health effects thought to be of most concern in regard to exposure to inorganic arsenic of the general U.S. population. Organic arsenic compounds are considered only insofar as certain forms of the element arise via transformation of arsenic in man and other species, or arise by environmental transformation.

This report is organized into chapters which provide a cohesive discussion of all aspects of inorganic arsenic and delineate a logical linking of this information to human health risk. The chapters include: an executive summary (Chapter 2) of the information contained within the text of later chapters; background information on the chemical and environmental aspects of arsenic, including levels of arsenic in media with which U.S. population groups come into contact (Chapter 3); arsenic metabolism, where factors of absorption, biotransformation, tissue distribution, and excretion of inorganic arsenic are discussed with reference to the toxicity of the element (Chapter 4); arsenic toxicology, discussing the various acute, subacute, and chronic health effects of inorganic arsenic in man and animals (Chapter 5); arsenic mutagenesis, discussing the ability of inorganic arsenic to cause gene mutations, chromosomal aberrations, sister chromatid exchanges and inhibition of DNA synthesis (Chapter 6); arsenic carcinogenesis, including discussion of selected dose-effect and dose-response relationships (Chapter 7); arsenic as an essential element, which deals with the current status of inorganic arsenic as a required nutrient in at least some species of animals (Chapter 8); and a human health risk assessment for arsenic, where key information from the preceding chapters is placed in an interpretive and quantitative perspective highlighting those health effects of most concern for U.S. populations (Chapter 9).

This report is not intended to be an exhaustive review of all the arsenic literature, but is focused upon those data thought to be most useful and relevant for human health risk assessment purposes. Particular emphasis is placed on delineation of health effects and risks associated with exposure to airborne arsenic, in view of the most immediate use intended for the present report, i.e., to serve as a basis for decision making regarding the regulation of inorganic arsenic as a hazardous air pollutant under pertinent sections of the Clean Air Act, as amended in 1977. Health effects associated with the ingestion of arsenic or with exposure via other routes are also discussed, providing a basis for possible use for multimedia risk assessment purposes, as well. The background information provided at the outset on sources, emissions, and ambient concentrations of arsenic in various media is presented in order to provide a general perspective against which to view the health effects evaluations contained in later chapters of the document. More detailed exposure assessments, taking into account even more recent, up-to-date emission and ambient concentration data have been prepared separately for use in subsequent EPA regulatory decision making regarding arsenic.

The Agency recognizes that the regulatory decision-making process is a continuous one; therefore, should new information become available in the future that would warrent a reevaluation of the information contained herein, the Agency will undertake such an evaluation as part of its mandate to protect the health of the general U.S. population.

REC 4912

TR 1597

2. SUMMARY AND CONCLUSIONS

As a toxic agent, inorganic arsenic possesses several properties that are not shared with many environmental pollutants. The element exists in various chemical states, e.g., tri- and pentavalent inorganic arsenic and methylated organic arsenic, with each having differing toxicological potential. In man, experimental animals, and other organisms, arsenic undergoes a variety of transformations, the full significance and mechanisms of which are, as yet, not well understood. Furthermore, there appears to be a nutritional requirement for low levels of arsenic in certain experimental animals and this may also be the case for man. All of these factors complicate the analyses of the toxicological effects and the risk for human health associated with environmental exposure to arsenic compounds. The following chapter summarizes these factors as they are presented in depth in the ensuing document text.

2.1 BACKGROUND INFORMATION

2.1.1 Chemical/Physical Aspects of Arsenic

It is the various compounds of arsenic which have been of most importance in the extensive history of the toxicology of the element, the zero-valent metallic form being of minor toxicological interest.

Arsenic is encountered as a component of sulfidic ores of metals such as copper, cobalt and nickel. The smelting of these ores is associated with arsenic release into the environment. Arsenic trioxide, As_2O_3, a toxicologically significant form, is a smelter product arising from air roasting of these sulfidic ores.

Arsenic trioxide, white arsenic, is only sparingly soluble in water and other solvents which do not promote chemical transformation. The compound dissolves in acidic or alkaline aqueous media to yield either the free acid or

salts, with these being soluble in a number of solvents. The oxide readily sublimes (135°C), and this factor is of importance in considering analytical methods for measuring levels of the compound.

The pentavalent arsenic pentoxide, As_2O_5, may be prepared by nitric acid oxidation of the trioxide or the element itself. This form has high solubility in water (63 g/100 g water), forming the strongly oxidizing arsenic acid, H_3AsO_4 ($E^o = 0.56V$).

Stability of the valency forms of arsenic in solution is dependent on the nature of the medium. Oxygenated media and higher pH favor the pentavalent form, while reducing and/or acidic media favor the trivalent state.

The acids of both valency forms of arsenic readily form alkali and alkaline metal salts, with the former being much more soluble than the latter. Organic ester derivatives of arsenic are quite labile to hydrolysis and this chemical behavior has biochemical/toxicological implications in the postulated role of arsenate ion in interfering with phosphorylation reactions.

Arsine (arsenic trihydride, AsH_3) is the most poisonous of the arsenicals, being a strong hemolytic agent, and it can be formed under certain restricted conditions, i.e., reduction of the oxy compounds in the presence of a strong hydrogen source.

Monomethyl and dimethyl arsenic arise by both environmental and *in vivo* transformation processes.

In high-temperature processes, arsenic is released as a vapor which is then adsorbed or condensed onto small particles. Such adherence to particles of 1-2 μm or less may result in enhanced health risk from the agent since particles in this size range are inhaled and deposited in the deepest part of the respiratory tract.

Arsenic compounds tend to form insoluble complexes with soils and sediments. In the case of soils, the interaction occurs with amorphous aluminum or iron oxides.

2.1.2 The Environmental Cycling of Arsenic

Primary smelting, biocide use and glass manufacturing constitute some of the major inputs of arsenic into the various environmental compartments. Of an estimated total release of approximately 10,000 short tons annually in the U.S., smelter activity accounts for about 50 percent, biocide (pesticide, fungicide, herbicide) use contributes 32 percent, and glass production contributes about 7.0 percent, with the remaining amount being released from various other sources.

The atmosphere is a major conduit for arsenic emitted from anthropogenic sources to the other environmental compartments via wet and dry precipitation processes. Dry and wet fall onto soils may be followed by movement through soils either into groundwater or surface water. Passage of arsenic into surface waters may be followed by transfer to sediments. Such cycling is made complex by chemical and biological transformations which have been reported as occurring in the various environmental compartments.

Trivalent arsenic in the atmosphere or in aerated surface waters can undergo oxidation to the pentavalent state, while pentavalent arsenic in media which are below pH 7.0 and contain oxidizable material can react to form the trivalent form via reduction.

Biological transformations of arsenic have been documented as occurring via both sedimentary bacteria and suspended marine algae. Several different hypotheses have been advanced to explain the biological cycling of arsenic.

Reduction and methylation of inorganic arsenic occur only to a limited extent in soils, one report noting a conversion of only 1-2 percent over a period of months.

With reference to the relative amounts of the annual environmental burden of arsenic, it has been calculated for 1974 that land is the major sink for arsenic, approximately 90 percent, with the atmosphere accounting for 7-8 percent and the smallest quantity appearing in waters.

2.1.3 Levels of Arsenic in Various Media

Available data on levels of arsenic in various media with which man interacts are generally presented as total arsenic, with limited information available for identifying specific chemical forms of arsenic.

2.1.3.1 Levels of Arsenic in Ambient Air--Based on the comprehensive data for U.S. air levels of arsenic obtained by the U.S. EPA's National Air Sampling Network, air levels of arsenic in the U.S. generally do not exceed 0.1 $\mu g/m^3$.

Generally, airborne arsenic is adhered to particulate matter. Although the immediate areas around smelters may contain some arsenic in the vapor form, data are available to indicate rapid adherence to particulate matter when sampling 2-3 km from these emission sites.

The specific chemical form(s) of airborne arsenic is still unclear. Generally, in most urban/suburban areas, arsenic is mainly in the form of a mixture of inorganic arsenic in the tri- and pentavalent states. Only in areas where methylated arsenic is used agriculturally or where biotic transformation can occur has methylated arsenic been found in air samples.

2.1.3.2 Levels of Arsenic in Drinking Water--The National Interim Primary Drinking Water Regulations, promulgated under the Safe Drinking Water Act, set the Maximum Contaminant Level (MCL) for arsenic in U.S. public water supplies at 50 µg/l. In general, arsenic is not found in drinking water at levels exceeding this MCL. Well waters in the western U.S. and Alaska, however, may have much higher levels owing to geochemical enrichment. In Lane County, Oregon, recent analyses report levels up to 2.2 ppm (2.2 mg/liter), while the

REC 4916

TR 1601

highest figure in Alaska was 10 ppm (10 mg/liter), representing both natural and mining residue contributions.

It is reasonable to assume that the chief chemical form of arsenic in most public water supplies would be the pentavalent inorganic form, owing to both aeration and chlorination. Similarly, well waters in Alaska and the western U.S. are reported to mainly contain pentavalent inorganic arsenic.

2.1.3.3 Arsenic in Food--The most recent data base for the arsenic content of foods is the 1975-1976 survey carried out by the U.S. Food and Drug Administration. Shellfish and other marine foods have the highest levels on a food category basis. Overall, the total dietary intake of arsenic in 1975-1976 was approximately 50 μg (elemental arsenic), representing an increase from the preceding years. Whether this increase represents a trend or merely reflects analytical variation in sampling from year to year is still to be determined.

The chemical forms of arsenic in foods are varied and complex. Crustaceans and other marine life store arsenic in complex organoarsenical forms which, based on recent reports, are assimilated by man and generally excreted intact. Toxicologically, these forms are comparatively inert.

2.1.3.4 Arsenic in Soils--Background soil arsenic levels range from less than 1 ppm to over 40 ppm, the latter reflecting agricultural practices as well as air fallout. Soil arsenic is usually bound to clay surfaces, and its mobility is a function of soil pH, phosphate levels, iron and aluminum content, and soil type. The mobile fraction, usually in the pentavalent form, is of concern in terms of movement to plants and water. Little reductive methylation occurs in most soils.

2.1.3.5 Other Sources of Arsenic--Limited data on arsenic content of tobacco suggest that more recent values range from around 1.5 ppm or less, while in the past (1945) values up to 40 ppm were measured. This decrease reflects reduced use of arsenical biocides in tobacco production.

REC 4917

TR 1602

2.2 ARSENIC METABOLISM

2.2.1 Routes of Absorption

Major routes of absorption of arsenic in the general population are inhalation and ingestion. The ingestion of arsenic may be either through the direct intake of food and water or through secondary intake via inhalation and swallowing. Arsenic uptake through the skin appears to be a minor route of exposure. Factors affecting the extent of absorption include chemical forms, particle size, and solubility.

2.2.1.1 Respiratory Absorption--Limited data from human subjects suggest that about 40 percent of most forms of inhaled arsenic is deposited in the lungs, all of which is eventually absorbed, yielding a net absorption of approximately 30 percent or greater of the inhaled amount.

Several studies of smelter workers also confirm that significant absorption of inhaled arsenic occurs, as judged by rapidly rising urine arsenic levels when exposure first occurs. Furthermore, the levels excreted are correlated with workplace air levels.

Animal data also indicate respiratory tract absorption when exposure occurs by inhalation of aerosols or by intratracheal instillation.

2.2.1.2 Gastrointestinal Absorption--Based on a number of reports using human subjects, soluble inorganic arsenic is almost totally absorbed from the gastrointestinal tract. Similar data have been obtained for such experimental animal species as the rat, pig, and monkey.

Less soluble forms of arsenic, such as arsenic trioxide in suspension, lead to considerably lower absorption while insoluble arsenic triselenide passes through the human GI tract with negligible absorption.

2.2.1.3 Transplacental Transfer--Transplacental transfer of arsenic in man appears to occur, based on autopsy data and on one report showing that newborn

REC 4918

TR 1603

cord blood levels approximate those of the mothers. Measurable levels of arsenic in fetal tissue have been determined by the fourth month of gestation, increasing to month seven.

In animals, inorganic arsenic appears to rapidly cross the placental barrier where it is distributed in embryonic tissue.

2.2.2 Biotransformation of Inorganic Arsenic In Vivo

An understanding of inorganic arsenic metabolism in man and other species is complicated by recently revealed biotransformation processes, discovered because of the development of analytical techniques which permit the chemical speciation of arsenic into its various forms. These processes not only relate to pharmacokinetic parameters such as tissue distribution and excretion, but also figure in the toxicology of the element. The two processes of significance for consideration here are the methylation of inorganic arsenic and oxidation-reduction interconversion of inorganic arsenic.

An extensive recent literature documents the in vivo methylation of inorganic arsenic to monomethyl and dimethyl arsenic (the latter being the major methylated metabolite) in every mammalian system studied to date, including man.

While the quantitative features of this phenomenon may vary among species, one can generally state that: 1) dimethyl arsenic is the major transformation product in both humans and animals, with the amount of monomethyl arsenic, when formed, being greater in humans; 2) methylation is assumed to be a route of detoxification, the methylated forms being not only much less toxic but also more rapidly excreted; 3) the methylating capacity of a given system can persist over a range of inorganic arsenic exposure but at some point can be overwhelmed; and 4) retrospective assessment of early data on arsenic

metabolism must be reviewed in light of the current knowledge about biomethylation. In man, dimethyl arsenic represents approximately 75 percent of total arsenic excretion, with monomethyl arsenic being excreted in lesser amounts.

The demonstration of interconversion of the two valency forms of inorganic arsenic claimed in earlier literature must be considered in light of the biomethylation phenomenon, and only more recent studies addressing this problem using chemical speciation techniques can be considered reliable. Invariably, the giving of inorganic penta- or trivalent arsenic to experimental animals or human volunteers leads to predominantly methylated forms, with any inorganic arsenic being present in small amounts. These observations and supporting data showing reduction of pentavalent arsenic in vivo are consistent with a reductive biomethylation mechanism, including initial reduction of pentavalent to trivalent arsenic prior to methylation. A recent study using speciation methods and human subjects also establishes the in vivo reduction of pentavalent to trivalent arsenic in humans.

Even with sophisticated analytical methods permitting chemical speciation in biological media, the lability of arsenic in dosing solution to oxidation-reduction requires careful assessment of the actual form being administered.

2.2.3 Distribution of Arsenic in Man and Animals

Blood is the main vehicle for transport of arsenicals following absorption, and from which arsenic is cleared relatively rapidly to tissues in all species except the rat. In the rat, arsenic-erythrocyte interaction tends to preclude rapid movement to tissues, with a biological half-time of up to 90 days, versus a corresponding time of several days in all other species. Arsenic movement from blood appears to conform to a three-compartment model which must reflect in part the biomethylation of inorganic arsenic noted above.

REC 4920

TR 1605

Exposure of various experimental animals to either tri- or pentavalent inorganic arsenic leads to initial accumulation of the element in liver, kidney, spleen, aorta, and skin. In most species, arsenic clearance from soft tissue is relatively rapid except for the skin, where the high sulfhydryl group content probably promotes tight arsenical binding.

In man, tissue partitioning data are mainly available from autopsy data. Heart, kidney, liver and lung have highest levels on a concentration basis, but skin and excretory/storage organs such as nails and hair have the highest absolute amounts. Brain tissue has levels only slightly below those of other soft tissues.

Recent data on valency and exposure level effects on tissue distribution of arsenic indicate that levels of arsenic in kidney, liver, bile, brain, skeleton, skin, and blood are 2- to 25-fold higher for the trivalent form than for the pentavalent state, and are greatly increased at higher dosing. The difference is held to be due to the relative methylating capacity of either form as well as the level of exposure.

2.2.4 Arsenic Accumulation

The long-held view of arsenic as an element which accumulates in the body was mainly based on the behavior of arsenic in the rat, an anomalous model which does not reflect the case with other species. For other species, including man, long-term accumulation does not generally occur in physiologically active compartments in the body.

In man, the only evidence for tissue accumulation is autopsy data from retired workers with a history of metal smelter exposure in which lung arsenic levels were 8-fold higher than in a control population. This suggests the existence of a very insoluble form of arsenic in smelter ambient air.

REC 4921

2.2.5 Arsenic Excretion

Renal clearance appears to be the major route of excretion of absorbed arsenic in man and animals. Biliary transport of the element leads to enteric reabsorption, with little carriage in feces.

In man, inorganic arsenic is excreted rather rapidly, and in several studies in which continuous exposure resulted in the acquisition of steady state, around 60 percent of a given dose was excreted within one day.

The pattern of renal excretion reflects the *in vivo* biotransformation capacity for inorganic arsenic, one study noting that trivalent arsenic was excreted more slowly than an equivalent dose of the pentavalent form, and higher doses of both forms were cleared relatively more slowly than lower doses.

2.3 ARSENIC TOXICOLOGY

2.3.1 Acute Toxicity

Acute symptoms of arsenic poisoning are similar in both man and experimental animals. With oral exposure, the acute symptoms include severe gastrointestinal damage resulting in vomiting and diarrhea and general vascular collapse leading to shock, coma, and death. Other acute effects are muscular cramps, facial edema, and cardiovascular reactions. Airborne exposure at high levels also results in severe irritation of nasal mucosa, larynx, and bronchi. Sequelae of acute contact with inorganic arsenic include peripheral nervous system disturbances with slow recovery and reversible effects on the hematopoietic system.

Levels of exposure associated with acute arsenic toxicity vary with the valency form of the element, the trivalent state being approximately 4-fold more toxic than pentavalent arsenic. Oral LD_{50} values for trivalent arsenic

REC 4922

TR 1607

vary from 15 to 293 mg/kg b.w. in rats and from 10-150 mg/kg in other test species.

While a number of outbreaks of acute arsenic poisoning have been described, few data exist on actual doses and type of arsenical involved. One report has estimated the human lethal dose for arsenic trioxide to be anywhere from 70 to 180 mg.

2.3.2 Chronic Toxicity

Two categories of chronic arsenic toxicity can be discerned from the available literature: 1) the mutagenicity/carcinogenicity of arsenic; and 2) various non-carcinogenic chronic effects.

2.3.2.1 Mutagenesis of Inorganic Arsenic--Various inorganic compounds of arsenic have been tested for mutagenicity in a variety of test systems ranging in complexity from bacteria to peripheral lymphocytes of exposed human beings. Although many of the data are contradictory, the weight of evidence supports the following conclusions:

1) Arsenic is either inactive or extremely weak for the induction of gene mutations in vitro.
2) Arsenic is clastogenic and induces sister chromatid exchanges (SCE) in a variety of cell types, including human cells in vitro; trivalent arsenic is approximately an order of magnitude more potent than pentavalent arsenic.
3) Arsenic does not appear to induce chromosome aberrations in vivo in experimental animals.
4) Several studies suggest that human beings exposed to arsenic demonstrate higher frequencies of SCE and chromosomal aberrations in peripheral lymphocytes; however, the quality of these studies is generally poor.

5) Arsenic may affect DNA by the inhibition of DNA repair processes or by its occasional substitution for phosphorus in the DNA backbone.

From these conclusions, it can be surmised that arsenic may have the potential to cause chromosomal changes in human beings. Although additional information is needed, it appears that the mutagenic potency of arsenic is weak compared to other known metal mutagens.

2.3.2.2 Carcinogenesis of Inorganic Arsenic--The current status of inorganic arsenic as a human and experimental animal carcinogen has been extensively and critically reviewed by public agencies such as the National Institutes of Occupational Safety and Health, scientific bodies such as the National Academy of Science and the International Agency for Research on Cancer, and in a number of individual assessments.

At present, the collective evidence for an etiological role of inorganic arsenic in human cancers is strongest for cancers of the skin and lung.

In man, chronic oral exposure to arsenic induces a sequence of changes in skin epithelium, proceeding from hyperpigmentation to hyperkeratosis characterized as keratin proliferation of a verrucose nature, and leading in some cases to late onset skin cancers. The skin cancers can be histopathologically characterized as either squamous carcinomas in the keratotic areas or basal cell carcinomas.

Arsenic-associated skin cancers, regardless of type of exposure, differ from those having an ultraviolet light etiology in that they occur on unexposed areas such as the palms and soles and occur as multiple lesions. The latency period for such lesions has been reported to range from 6 to 50 years for skin cancer induced by the administration of arsenical medicinals. The most reliable study of skin cancer associated with arsenic-contaminated drinking water found the minimum human latency period to be 24 years.

REC 4924

TR 1609

Lung cancers associated with occupational exposure to arsenic appear to be mainly of the poorly differentiated and small-cell undifferentiated epidermoid carcinoma type, although well-differentiated epidermoid carcinoma and acinar-type adenocarcinoma have also been noted. The latency period for such lung cancer due to occupational arsenic exposure at smelters has been reported to range from 13 to 50 years.

While other visceral cancers such as hepatic angiosarcomas have also been claimed to be associated with arsenic exposure, the data base for such association is less conclusive than for cancers of the skin and lung.

2.3.2.2.1 Human Epidemiology of Arsenic Carcinogenesis. Cancer- and possible precancerous lesion-producing inorganic arsenic exposures have been demonstrated in both occupational populations, such as copper smelters, pesticide manufacturers and argricultural workers, and in non-occupational populations using arsenical drugs or consuming arsenic-contaminated drinking water and/or food.

Cancer or possible precancerous skin lesions associated with arsenic exposure include lung cancer, skin cancer, peripheral vasculopathy, hyperkeratosis, hyperpigmentation, and depigmentation. Of these, cancers of the lung and skin have received the most attention. Furthermore, epidemiologic reports of cancer or possible precancerous lesions related to arsenic exposures have a wide geographical distribution, with studies reported in the United States, Europe, Asia and South America.

Lung Cancer

An excess mortality in respiratory cancer has been noted among smelter workers and among workers engaged in the production and use of arsenical pesticides. In a number of these studies, the levels of exposure are uncertain and there is simultaneous exposure to agents such as other metals and sulfur dioxide. Furthermore, some of these studies did not take into account the effects of cigarette smoking.

REC 4925

TR 1610

A proportionate mortality study of an English factory which manufactured arsenite as a sheep dip powder found that workers at the facility had a proportion of lung cancer deaths twice that for other workers in the geographic area. Of the total factory group, the chemical workers, who were the most closely associated with the arsenite production, accounted for all of the lung cancer deaths and had a higher proportion of deaths from all cancers than the total factory population. Air exposure information was limited, levels up to 4 mg As/m^3 having been reported only for 1945-1946. The outcome of the earlier English study has been supported by studies of two facilities in the United States. At one facility manufacturing lead-, calcium-, and magnesium arsenate and copper acetoarsenite over the period 1919-1956, the ratio of observed-to-expected lung cancer deaths among workers was evaluated on the basis of exposure level, giving ratios ranging up to 7:1 in the highest exposure category.

The second U.S. facility, in Baltimore, Maryland, has been the subject of two occupational studies. At this operation, production of lead-, calcium-, and sodium arsenate was started in the early 1950s. Air levels of arsenic were not available. In the most recent report--a follow-up of workers employed from 1946 to 1974--statistically significant increases in lung cancer deaths were found in "predominantly arsenical production workers." Information on smoking history was not obtained.

Occupational exposure to arsenic also occurs in smelters. Several reports have centered on workers at a copper smelter in the state of Washington. In the most recent publication concerning cancer deaths at this facility, an increase in overall mortality, a significant increase in cancer deaths, and a highly significant increase in deaths from lung cancer were noted. Although

REC 4926

TR 1611

cigarette smoking data were not available, a clear lung cancer dose response by arsenic exposure was found, suggesting that smoking probably did not confound the lung cancer response believed to be due to arsenic.

Other U.S. studies have been done at smelter sites in Utah and Montana. In the Utah study, smelter workers showed a 3-fold increase in the lung cancer death rate compared to the general population of the state. Exposures to sulfur dioxide and copper, as well as arsenic, were found to be significantly higher for the lung cancer cases. Differences in smoking habits could not explain the excess lung cancer mortality. Smelter workers at the Montana smelter were found to follow a lung cancer dose response by arsenic exposure. Differences in smoking habits could not explain the differences in lung cancer mortality. Little association, if any, was found between sulfur dioxide exposure and lung cancer mortality.

Some of the evidence from the U.S. smelter studies suggests that arsenic may be acting as either a late-stage carcinogen in the multistage theory of carcinogenesis or as a promoter in the carcinogenesis process. Either hypothesis requires further study, however.

Excess lung cancer mortality has also been reported for workers in foreign smelters. Several reports have concerned the smelter facility in Sweden. In this operation, it was found that arsenic exposure was associated with increases in lung cancer deaths, the ratio being 4.6 for a work history of more than 17 years. Sulfur dioxide exposure was not found to be associated with lung cancer, nor could the results be explained by differences in smoking habits. A study of smelter workers in Japan has also reported a positive association between smelter employment and lung cancer. Workers in the highest exposure and longest follow-up category were reported to have a 25-fold increase in lung cancer mortality.

REC 4927

TR 1612

Several studies suggest that populations surrounding arsenic-emitting sources are at a greater risk of lung cancer. One study found that lung cancer in counties with smelters was significantly higher than in counties without smelters. Another study found an association between residence in an area surrounding an arsenic pesticide plant and lung cancer mortality even after controlling for employment at the pesticide plant. Two lung cancer mortality studies of populations in the vicinity of smelters are inconclusive with regard to lung cancer risk in the general population because lung cancer deaths of workers at the smelters were included in the analyses. It should be noted that none of these studies addressed the effects of population migration, however.

Skin Cancer and Precancerous Lesions

All of the occupational studies on arsenic have been mortality studies. Because skin cancer is rarely fatal, the occupational studies, in general, do not report excesses of skin cancer. The English study referred to in the preceding section, however, did note that cancer deaths among those factory workers with skin cancer was 13.6 percent compared to a figure of 1.3 percent in the reference population.

Most of the available information on the association of arsenic with skin cancer has involved non-occupational populations in geographical areas as diverse as Taiwan, Argentina, and northern Europe, and has involved arsenic in drinking water or medicinal preparations.

In Taiwan, exposure started in 1910-1920 with the availability of water from deep wells. In the most comprehensive study of this group, 37 villages with a population of 40,421 were surveyed in 1965 and the prevalence rate of skin cancer was categorized by arsenic exposure and age. The prevalence rate of skin cancer increased with both well water arsenic and age. The greatest

REC 4928

TR 1613

prevalence rate was in the >60-years age group (192.0/1,000 subjects) exposed to well water with an arsenic content of >0.6 ppm. There was a similar ascending gradient for hyperkeratosis, an apparent precondition for the later onset of skin cancer.

In Cordoba, Argentina, arsenical waters have also been reported to be associated with increased rates of skin cancer among the population using this water. In the various reports on this area, it has been noted that over 81 percent of persons with "arsenical-type" skin epitheliomas presenting themselves at a particular dermatology clinic came from areas where high levels of arsenic were known to be present in the water supplies and where arsenicism among individuals was known to occur. Lack of information on the size of the populations in each geographic area limits the conclusions that can be drawn from these studies, however.

In a number of epidemiological surveys conducted in Antofagasta, Chile, the presence of a relatively high level of arsenic, 0.6 ppm, in the public drinking water from 1958 to 1970, was shown to have resulted in a high number of skin lesions including hyperkeratosis which may be a precondition for skin cancer. In one report of cases seen and diagnosed from 1968 to 1971 in Antofagasta, the author reported 457 patients with various cutaneous lesions including leukoderma, melanoderma, hyperkeratosis, and squamous-cell carcinoma; all had high arsenic content in the hair. The number of cases for each diagnosis was not specified.

An investigation of the population having contact with well waters containing elevated levels of arsenic in an area of Oregon did not yield any evidence for skin cancer associated with such exposure, nor did a similar study in Utah. Factors which may have contributed to the difference in results between these studies and the studies in Taiwan, where an association between

skin cancer and arsenic in drinking water was found, include: (1) in addition to arsenic, ergotamine was found in the Taiwan drinking water, (2) the socioeconomic level of the Taiwanese who experienced skin cancer was rather low, which may have had ramifications in terms of diet, personal hygiene and medical care, and (3) racial differences between the Taiwanese and U.S. populations may have had an effect. However, the population sample sizes of the Oregon and Utah studies were too small to detect the risk from skin cancer that would have been predicted, on the basis of arsenic ingestion, from a linear model of the Taiwanese data.

The chronic ingestion of trivalent arsenic present in the medicinal preparation, Fowler's Solution, has been shown to be associated with the typical arsenic dermatopathology, including skin cancer. In one detailed study of patients with a history of Fowler's Solution use, 21 cases of skin cancer and 106 cases of hyperkeratoses were found among 262 subjects. Both the hyperkeratosis and skin cancer prevalence rates were found to increase as the total ingested amounts of the arsenical increased. The minimal latency period for hyperkeratosis was 2.5 years while the minimal latency period for skin cancer was 6 years, with an average of 14 years.

Internal neoplasms associated with arsenic exposure have been reported in subjects exposed to medicinal arsenic as well as in such occupational groups as vintners and smelter workers.

2.3.2.2.2 Experimental studies of arsenic carcinogenesis. Consistent demonstration of arsenic carcinogenicity in test animals, using different chemical forms, routes of exposure, and various experimental species, has not been observed. Part of the difficulty may lie in the selection of an appropriate animal model. The absence of skin cancers in the experimental animals used could be accounted for by their skin being poor models of human skin. Rat

REC 4930

TR 1615

results must be considered suspect because the rat is anomalous in how it metabolizes arsenic.

Recent data indicate that tumorigenicity and possibly carcinogenicity can be demonstrated in animals if the retention of arsenic in the lung is increased. The additional observations that calcium arsenate, as reported from two laboratories, is only slowly cleared from the lung, strongly suggest that this agent may be carcinogenic.

2.3.2.3 Chronic Neurological Effects of Arsenic Exposure--Both peripheral and central nervous system effects have been documented in man and animals exposed to inorganic arsenic.

Peripheral nervous system effects have been noted in workers occupationally exposed to arsenic and in individuals accidentally exposed to food contaminated with arsenic. Some of these effects follow an insidious course, appearing months or years after onset of exposure. Effects are of both the sensory and motor types, sensory deficits manifesting themselves first. The resulting polyneuropathies tend to follow a slow course of recovery over months or years. More subtle neurological effects, such as neuromuscular disturbances and altered nerve conduction velocity, have also been reported by various investigators.

While there are documented cases of central nervous system (CNS) effects in children due to acute or subacute exposure, chronic arsenic intoxication as a factor in such abnormalities as hearing impairment has not been confirmed.

Few useful animal models exist for the central and peripheral nervous system effects seen in humans. One study has reported evidence of CNS functional deficits in rats exposed to arsenic trioxide aerosol, while a second report claims impaired behavioral responses in rats given arsenic trioxide via stomach intubation. Since rats handle arsenic differently than all other species, the significance of these data is not clear.

2.3.2.4 Cardiovascular Effects of Arsenic Exposure--Cardiovascular effects associated with chronic arsenic intake include Blackfoot disease seen in Taiwanese consuming well water having elevated arsenic. This is a peripheral vascular disease leading to gangrene of the extremities. Since ergotamine-like compounds were also present in the waters, the conclusive role for arsenic is not clear. Peripheral vascular changes have been documented among German vintners who were exposed occupationally to arsenic pesticides as well as arsenic in wine.

2.3.2.5 Other Systemic Effects of Arsenic--Non-cancerous respiratory effects of inorganic arsenic are mainly seen with occupational exposure and with arsenic trioxide. In one study of smelter workers, those handling refined arsenic showed nasal septum perforation and rhinopharyngolaryngitis, while workers in roaster, furnace, and convertor areas showed tracheobronchitis and pulmonary insufficiency.

Teratogenic effects of arsenic compounds at relatively high exposure levels have been demonstrated in a number of animal species, including hamsters, rats, and mice. Generally, such effects have been observed after parenteral administration of either arsenite or arsenate. Oral exposures of animals to these same arsenic compounds at lower doses, by contrast, have not been shown to produce any notable effects on reproduction and development. Methylated arsenic, while potentially teratogenic at high doses, is of lower potency than inorganic forms. There is little evidence that inorganic arsenic is a human teratogen.

Hepatic effects have been noted in a number of studies dealing with chronic intake of arsenic. These disturbances present as cirrhosis and portal hypertension. One complicating factor in occupational exposure assessment has been the effect of alcohol consumption.

REC 4932

TR 1617

Chronic exposure to arsenic via well water contaminated by arsenic, medicinals, or the workplace, produces a reversible anemia. Rats, mice, and cats fed either arsenite or arsenate show reduced hemoglobin production via disturbance of the ALA-synthetase and heme-synthetase steps in the heme biosynthetic pathway.

Renal effects seen with arsenite or arsenate exposure in either man or animals have been poorly characterized.

2.3.3 Factors Affecting Arsenic Toxicity

The most widely recognized and studied interactive behavior of arsenic is with selenium, the pair being antagonistic in effect in all animal species studied. Dietary arsenic supplementation is known to protect against selenium toxicity, while selenium protects against either tri- or pentavalent arsenic. Arsenite shows a protective effect for selenite toxicity in cell cultures, but the reverse does not appear to be the case.

Few data exist for interactive relationships between arsenic and other elements. One report notes that cadmium and arsenic given simultaneously by the oral route retarded weight gain in young adult rats to a greater extent than either element given alone.

2.4 ARSENIC AS AN ESSENTIAL ELEMENT

Inorganic arsenic appears to be an essential element in certain animal species--rats, goats, chicks, and minipigs--based on the observation of detrimental effects using diets deficient in the element.

In rats, arsenic-deficient diets in pregnant dams are associated with slow growth, enlarged spleens, erythrocyte dysfunction in post-weaning offspring, and greater perinatal mortality.

In studies using goats and minipigs, diets having less than 50 ppb As produced effects in the adult animals as well as in their offspring. Morta-

REC 4933

TR 1618

lity of adult goats was increased as was the mortality of both kids and piglets. In chicks, arsenic deprivation influenced the effects of dietary arginine, manganese, and zinc, the fluctuations of which variously affected metabolic activity.

Remaining to be independently demonstrated are a physiological role for arsenic, the existence of any specific carrier in the body, or arsenic essentiality in man.

2.5 HUMAN HEALTH RISK ASSESSMENT FOR ARSENIC

This portion of the summary contains the data summarized earlier, presented within a perspective of the possible quantitative risk posed to the general population of the United States by arsenic exposure. Categories of consideration include: (1) levels of arsenic in media relevant to the U.S. population; (2) those effects relevant to the general population; (3) indicators of exposure, specifically "internal dose" measures; (4) dose-effect and dose-response relationships which can be determined from available information; and (5) the identification of groups within the general population who may be at increased risk for the health effects of arsenic.

2.5.1 Exposure Aspects of Arsenic

Arsenic exposure in the general population of the United States occurs via inhalation and ingestion of water and food.

Respiratory intake of arsenic on a daily basis is approximately 0.12 μg, of which 0.03 μg would be absorbed, assuming 30 percent absorption and based on a 1981 national average air value of 0.006 $\mu g/m^3$ of air and a daily ventilation rate of 20 m^3.

Since much of the U.S. drinking water supply is below the 10 μg/liter level, daily consumption of water at a rate of 2 liters would lead to an intake $\leq$ 20 μg.

REC 4934

TR 1619

Based on 1975-76 figures from the Food and Drug Administration, daily arsenic intake from food is approximately 50 μg (elemental arsenic) for adults. If one assumes at least 80 percent absorption of this daily intake, approximately 40 μg is the absorbed amount. It should be noted, however, that arsenic in certain foods is known to be in a chemically complex form that is relatively resistant to metabolism and toxicologically inert; consequently, it is rapidly excreted intact. Therefore, the amount of absorbed food arsenic considered to be toxicologically significant is relatively small compared to total arsenic intake.

Cigarette smoking contributes about 6 μg/pack of cigarettes in mainstream smoke, of which approximately 2.0 μg/pack would be absorbed.

Thus, the aggregate absorbed amount is approximately $\leq$ 60 μg for non-smokers. However, the actual amount of toxicologically significant arsenic taken in daily would probably be closer to 20 μg or less.

2.5.2 Effect/Response Aspects of Arsenic

2.5.2.1 Relevant Health Effects--General population concerns are with effects arising from long-term exposure to moderate levels of arsenic.

One can rank health effects germane to the general population as follows:

1. Respiratory tract cancer.
2. Skin cancer.
3. Non-cancerous skin lesions.
4. Peripheral neuropathological effects.
5. Cardiovascular changes.

Cancer of the respiratory system is clearly associated with exposure to arsenic via inhalation. This association has been especially noted among workers engaged in the production and usage of pesticides and among smelter workers. The latency period for lung cancer due to occupational arsenic exposure has been reported to range from 13 to 50 years.

Cancer of the skin has been found as a dose-dependent effect in a Taiwanese population with lifetime exposure to well water arsenic as well as among people who were treated with large doses of arsenite for skin disorders. Arsenic-associated skin cancers occur on areas of the body generally unexposed to the ultraviolet light of the sun, such as the palms of hands and soles of feet. The latency period for skin cancer has been reported to range from 6 to 50 years for cancers induced via administration of arsenical medicinals. In the Taiwanese drinking water study, the minimum latency period was reported to be about 24 years.

The Carcinogen Assessment Group (CAG) of the U.S. Environmental Protection Agency (EPA) has concluded that there is sufficient evidence that inorganic compounds of arsenic are both lung and skin carcinogens in humans.

Hyperkeratosis and hyperpigmentation, sometimes with precancerous changes, have been a common finding in persons ingesting arsenic. These skin lesions, like the manifest cancer, develop on surfaces usually unexposed to sunlight.

Peripheral nervous system effects range from sensory-motor deficits with higher exposure to changes in electromyography and nerve conduction velocity at long-term, low levels of contact with arsenic.

Vascular effects, such as Blackfoot disease (peripheral vasculopathy) have been noted in a Taiwanese population having life-long arsenic exposure; however, these effects may have been confounded by the presence of ergotamine-like compounds. Peripheral vascular changes have also been found in German vintners exposed occupationally to arsenic pesticides as well as arsenic in wine.

2.5.2.2 Dose-Effect/Dose-Response Relationships--The general question of how to define and employ a dose factor in attempts at quantitative assessments of human health risk for any toxicant is highly dependent upon: 1) the available

REC 4936

TR 1621

information on the body's ability to metabolize the agent, and 2) the assessment of the relative utility of various internal indices of exposure.

The time period over which a given total intake occurs is highly important. For example, intake of one gram of arsenic over a period of years would be quite different pathophysiologically from assimilating this amount at one time, the latter probably having a lethal outcome. This time-dependent behavior is related in part to the relative ability of the body to detoxify inorganic arsenic by methylation as a function of both dose and time.

In cases of acute and sub-acute exposure, indicators of internal exposures, such as blood or urine arsenic levels, are probably appropriate for assessing the intensity of exposure.

With chronic low-level exposure, however, the available data would indicate that the total amount assimilated is probably more important than an indicator concentration without knowledge of the total exposure period. An added problem is the background level of arsenic found in some indicators due to dietary habit. Therefore, in low-level chronic exposures, arsenic levels in blood or urine would only be moderately increased over background levels. Hair arsenic levels cannot be employed as reliable indicators of exposure because no methods exist for distinguishing external contamination levels from those accumulated via absorption and metabolic distribution.

Given the above limitations concerning the use of blood, urinary or hair arsenic concentrations as internal indices of cumulative, long-term low-level arsenic exposure, the dose-effect/dose-response relationships summarized below are done so mainly in terms of external arsenic exposure levels via either inhalation or ingestion.

From available data, the Carcinogen Assessment Group (CAG) has estimated carcinogenic unit risks for both air and water exposures to arsenic. The

REC 4937

TR 1622

quantitative aspect of carcinogen risk assessment is included here because it may be of use in setting regulatory priorities, evaluating the adequacy of technology-based controls, and other aspects of the regulatory decision-making process. However, the imprecision of presently available technology for estimating cancer risks to humans at low levels of exposure should be recognized. At best, the linear extrapolation model used (see Section 7.3) provides a rough but plausible estimate of the upper limit of risk--that is, with this model it is not likely that the true risk would be much more than the estimated risk, but it could be considerably lower. The risk estimates presented below should not be regarded, therefore, as accurate representations of true cancer risks even when the exposures involved are accurately defined. The estimates presented may, however, be factored into regulatory decisions to the extent that the concept of upper-risk limits is found to be useful.

The air estimates were based on data obtained in five separate studies involving three independently exposed worker populations. Linear and quadratic response models in both the absolute and relative form were fitted to the worker data. It was found that for the models that fit the data at the $p = 0.01$ or better level, the corresponding unit risk estimates ranged from 1.05×10^{-4} to 1.36×10^{-2}. However, linear models were found to fit better than quadratic models and absolute models fit better than relative models. The CAG also felt that exposure to trivalent arsenic was more representative of low environmental exposure than pentavalent arsenic. Restricting their unit risk estimates to those obtained from linear absolute models where exposure was to trivalent arsenic gave a range of 1.25×10^{-3} to 7.6×10^{-3}. A weighted average of the five estimates in this range gave a composite estimate of 4.29×10^{-3}.

REC 4938

TR 1623

The unit risk estimates for water were based on an extensive drinking water study which was conducted in a rural area of Taiwan. An association between arsenic in well water and skin cancer was observed in the study population. Using the male population, who appeared to be more susceptible, the CAG estimated that the unit risk associated with drinking water contaminated with 1 µg/ℓ of arsenic was 4.3×10^{-4}.

To compare the air and water unit risks, the CAG converted the exposure units in both cases to mg/kg/day absorbed doses, which resulted in unit risk estimates of 50.1 and 15.0, respectively.

The potency of arsenic compared to other carcinogens was evaluated by noting that an arsenic potency of $2.25 \times 10^{+3}$ $(\text{mMol/kg/day})^{-1}$ lies in the first quartile of the 52 suspect carcinogens that have been evaluated by the CAG.

The U.S. EPA is presently examining information from studies on both patient and general populations which have been exposed to arsenic via medicinals or drinking water, respectively, in order to determine whether quantitative dose-response relationships can be established for non-cancerous skin lesions.

While the qualitative evidence for peripheral neurological effects and cardiovascular changes in arsenic-exposed populations is well established, the data are insufficient for determining quantitative dose-response relationships at the present time.

2.5.3 Populations at Special Risk to Health Effects of Arsenic

From a Japanese study, which reported on the poisoning of children exposed to arsenic in infant milk formula, young children may be considered at risk for acute exposure to arsenic. From the clinical reports published at the time of the mass poisoning, as well as those from follow-up studies, a

REC 4939

TR 1624

number of signs of central nervous system involvement were noted at both the time of the episode and much later, with the follow-up studies showing behavioral problems, abnormal brain wave patterns, marked cognitive deficits, and severe hearing loss.

Because children consume more water per unit body weight than do adults, the daily intake of arsenic via drinking water per kilogram body weight would be greater in children. This might have implications regarding chronic exposure effects in children. However, it should be noted that serious health effects due to chronic exposure of arsenic in drinking water have not been found at a greater frequency in children than adults.

Individuals residing in the vicinity of certain arsenic-emitting sources, e.g., certain types of smelters, may be at risk for increased arsenic intake because of both direct exposure to arsenic in air and indirect exposure via arsenic secondarily deposited from air onto soil or other human exposure media. The relative contribution from such indirect exposures to increased risk would be difficult to define, however.

A less defined group at risk would be cigarette smokers due to some arsenic in tobacco, but it is not clear just what the quantitative increase in risk would be.

REC 4940

TR 1625

3. BACKGROUND INFORMATION

3.1 CHEMICAL/PHYSICOCHEMICAL ASPECTS

Compounds of arsenic in various chemical forms have most prominently figured in the extensive history of the toxicology of the element. The physical properties for several of these compounds are presented in Table 3-1. In contrast, the element in the metallic, zero-valent form is of minor toxicological interest.

Geochemically, arsenic is encountered as a component of sulfidic ores, occurring as the arsenides and diarsenides of metals such as nickel, cobalt, and copper, and is present in rocks and soils at trace levels. Smelting of commercially important metal ores, therefore, often has associated with it the release into the environment of significant quantities of certain arsenic compounds. For example, arsenic trioxide, As_2O_3, a major form of the element in terms of its toxicological history, is a smelter product arising from air roasting of metallic arsenides or arsenic-containing sulfides.

Arsenic trioxide, white arsenic, is only slightly soluble in water and other solvents which do not promote chemical transformation. Its solubility in solvents which mimic physiological media may not necessarily be the same as for simple solvents, e.g., gastric juice versus water. Arsenic trioxide sublimes, the process becoming pronounced at 135°C. This property appears to have been overlooked through the years in considering analytical methods for measuring levels of the compound. Dissolution of the trioxide in aqueous media leads to formation of arsenous acid, H_3AsO_3, while alkaline treatment leads to formation of the arsenite ion, $AsO(OH)^-_2$, with both the acid and the salt being freely soluble in a number of solvents.

TABLE 3-1. PHYSICAL PROPERTIES OF ARSENIC AND ARSENIC COMPOUNDS

Chemical name	Atomic/ molecular weight	Melting point (°C)	Boiling point (°C)	Density (g/cm^3)	Crystal system	CAS Number

Arsenic pentoxide, As_2O_5, may be readily prepared by nitric acid oxidation of elemental arsenic or the trioxide. Compared to the trioxide, the pentoxide has considerable solubility in water (63.0 g/100 g water), presumably dissolving to form the relatively strong arsenic acid, H_3AsO_4. In acid media, arsenic acid has oxidizing potential (E^o=0.56V).

The relative stability of solutions of arsenic or arsenous acids to oxidation-reduction is of considerable importance in terms of valency-dependent arsenic toxicity. In oxygenated media, one would expect the pentavalent form to dominate, while reducing media would favor the trivalent state.

Arsenous and arsenic acids both form mono-, di- and tri-metal salts, the alkali-metal salts such as potassium and sodium arsenite being freely soluble in water and the alkaline salts such as calcium or magnesium arsenite being slightly soluble.

While tri-organic esters of the tri- and pentavalent arsenic acids are known, they are labile to hydrolysis and one would expect the mono- and di-organic derivatives to be even more so. This behavior has implications in the postulated role of arsenate ions in interfering with phosphorylation reactions.

Arsine (arsenic trihydride, AsH_3) is a strong hemolytic toxicant and probably the most poisonous of the arsenicals. Although generally a minor factor in the environmental chemistry of arsenicals, it can form under certain restricted conditions, i.e., via reduction in the presence of an active hydrogen-generating source.

Monomethyl and dimethyl arsenic, in the form of methylarsonous and methyl arsonic, dimethylarsinous and dimethylarsinic (cacodylic) acids, occur both in the environment and are formed via <u>in vivo</u> transformation in many mammalian

species, including man. Such organic arsenic compounds are also of commercial significance. For instance, both methylarsonic and dimethylarsinic acids, usually in the form of the mono- or dialkali salts, are employed as herbicides which, when released into the environment, may undergo reduction to the corresponding labile arsine compounds, CH_3AsH_2 (methylarsine) and $(CH_3)_2$ AsH (dimethylarsine) (Arsenic. NAS, 1977). Like trivalent inorganic arsenic, methylarsonous acid can interact with thiol groups (as can cacodylic acid) to form the CH_3-As(-S-)$_2$ and $(CH_3)_2$-As-S groups, respectively. The physical forms of arsenic in the environment depend on its mode of emission and subsequent interactions with other materials.

Arsenic, along with other trace metals, can be mobilized in association with airborne particles derived from high-temperature sources such as fossil-fueled power plants, metallurgical smelters and blast furnaces.

Arsenic compounds form insoluble complexes with soils and sediments. With soils, the interaction involves clay surfaces containing amorphous aluminum or iron oxides (Woolson, 1976).

3.2 ENVIRONMENTAL CYCLING OF ARSENIC

Inorganic arsenic is released into the environment from a number of anthropogenic sources which include primary copper, zinc and lead smelters, glass manufacturers (specifically those that add arsenic to the raw materials) and arsenic chemical manufacturers. Figure 3-1 presents a generalized scheme for the geochemical cycling of arsenic through various compartments of the environment. The atmosphere is a major conduit for arsenic emitted from anthropogenic sources to the balance of the cycle via wet and dry precipitation processes. The rate of movement of arsenic from the atmosphere is not known at present.

REC 4944

TR 1629

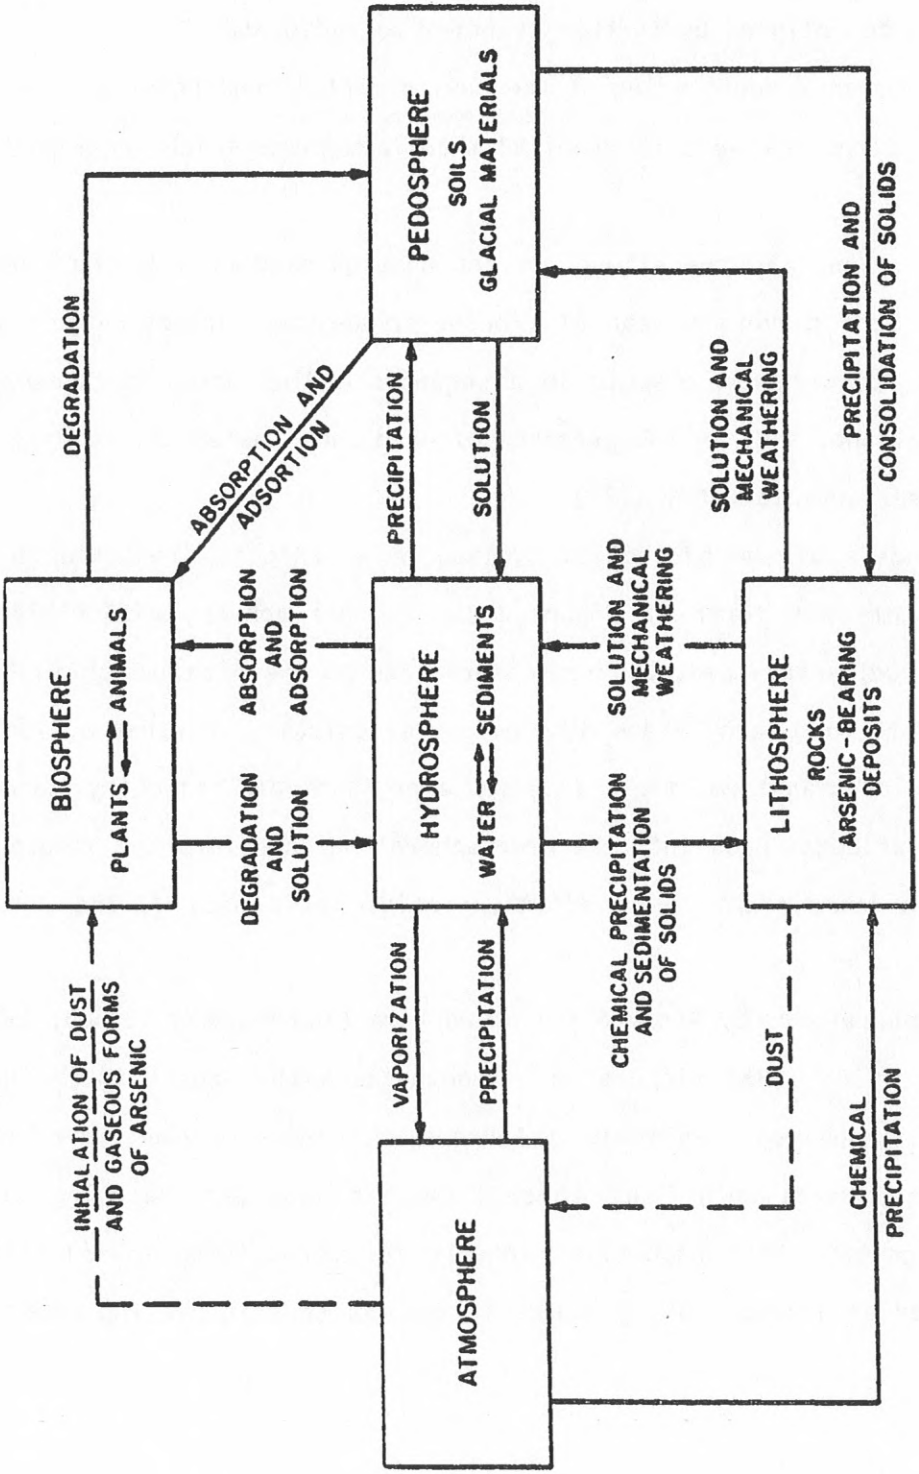

Figure 3-1. The generalized geochemical cycle for arsenic.

Source: Union Carbide (1977).

REC 4945

TR 1630

Dry and wet fall onto soils may be followed by movement through soils either into ground water or surface water. Passage of arsenic into surface waters may then be followed by further transfer to sediments.

Complicating an understanding of the environmental cycling of arsenic is the existence of chemical and biochemical transformations which occur within the cycle.

Trivalent arsenic in the atmosphere can undergo oxidation to the pentavalent state. Such conversion can also occur in aerated surface waters. On the other hand, pentavalent arsenic in an aqueous medium which is somewhat acidic is an oxidant, and, in the presence of oxidizable material, it will react to form trivalent arsenic (NAS, 1977).

One hypothesis of the biological cycling of arsenic is presented in a generalized scheme set forth in Figure 3-2. In this scheme, Wood (1974) proposes that sedimentary bacteria reduce arsenate to arsenite, which in turn may be altered to form methyl- and dimethyloxy arsenicals. Further action of bacteria and molds transforms these intermediates to di-and tri-methyl arsine. These volatile products pass into the hydrosphere and then into the atmosphere, where oxidative transformation to dimethyl-arsinic acid and, further, to inorganic arsenic occurs.

More recent reports by Andreae and co-workers (Andreae and Klumpp, 1979; Andreae, 1979; 1980; 1983) dispute this hypothesis with respect to marine environments. In analyses performed by Andreae and other workers, no volatile organoarsenic compounds were found to be formed in seawater, negating the hypothesis suggesting that reductive biomethylation resulting in volatile compounds serves as a contributing source to the atmospheric cycling of arsenic.

REC 4946

TR 1631

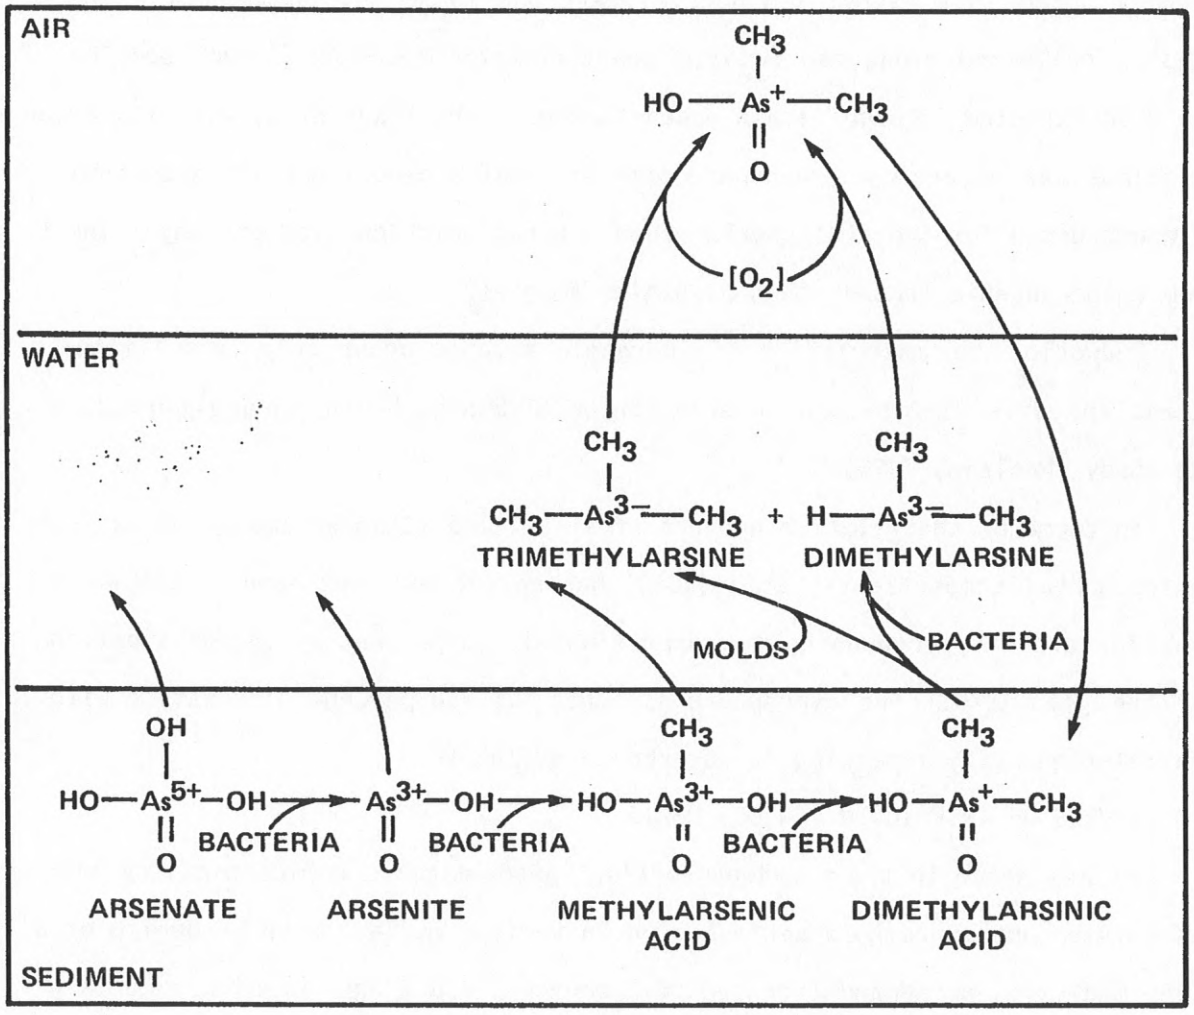

Figure 3-2. The proposed biological cycle for arsenic.

Source: Wood (1974)

While the authors did note the occurrence of biomethylation, the observed products were non-volatile, water-soluble methylated oxoacids of low toxicity. Further, the site of biotransformation was reported to be planktonic algae residing in the photic zone, rather than sedimentary bacteria. Similarly, the authors noted that methylated species were not found in a number of rain samples collected along the Pacific coast between 1976-1978. Such species would be expected if significant ocean-to-atmosphere transfer by biomethylation reactions was occurring. Andreae suggested that a global mass balance could be constructed for the atmospheric arsenic cycle which derived its major input from anthropogenic, rather than biogenic, sources.

Reduction and methylation of inorganic arsenic occur only to a limited extent in soils, 1-2 percent over a period of months having been reported in one study (Woolson, 1976).

In terms of the relative amounts of arsenic partitioned among the various environmental compartments, Suta (1980) has calculated that land is the major sink for arsenic, accounting for approximately 90 percent of the dissipation for the year 1974. The atmosphere accounts for 7-8 percent dissipation with the least quantity appearing in waterborne effluents.

3.3 LEVELS OF ARSENIC IN VARIOUS MEDIA

As was noted in the previous section, geochemical and biological cycling mechanisms contribute to arsenic burden in various media. Such burdening of a given medium is augmented from specific sources, e.g., agro chemicals containing arsenic applied to agricultural lands.

Available information on the arsenic content of media with which man interacts is generally in the form of total amounts of the element, with limited data available for assessing specific chemical forms. Since the toxicity of arsenicals varies with chemical form, any supporting data for determining chemical states will be discussed in this report, however fragmentary.

REC 4948

TR 1633

3.3.1 Levels of Arsenic in Ambient Air

The most comprehensive data for ambient air levels of arsenic in the U.S. are those of the National Air Sampling Network conducted by the U.S. EPA. Measurements from this network are summarized in Table 3-2. All values were determined from nuclear activation analysis of individual 24-hour high volume particulate samples. As shown in Table 3-2, the number of observations available is considerably different from year to year. This is due to changes in the participation of state and local agencies operating the individual sites and, for the year 1981, only about half the samples collected have been analyzed and reported into the network data base at this time. Thus, direct comparison of the summary statistics from year to year may be of limited utility.

A closer examination of the NASN data by site indicates that in areas not influenced by copper smelters, maximum 24-hour concentrations do not exceed 0.1 $\mu g/m^3$. There are only two exceptions of approximately 600 site/years represented in the table where there were observations above 0.1 $\mu g/m^3$--Omaha, Nebraska, and Charleston, West Virginia. The site in Charleston ceased operation after 1978; therefore, it is difficult to interpret the single value above 0.1 $\mu g/m^3$. Repeated observations above 0.1 $\mu g/m^3$ have occurred at the site in Omaha, Nebraska.

Using the NASN data base, U.S. annual arithmetic mean arsenic concentrations are plotted in Figure 3-3. The plot suggests considerable variability over the five-year period with no clear direction of trend. Perhaps the most striking feature in the data is the relatively low annual arsenic level observed in 1980. A partial explanation for this observation may be the strike which idled most of the nation's copper smelters from June through September of 1980 (Eldred et al., 1983).

REC 4951

TR-1636

The locations of these primary copper smelters in the U.S. are listed in Table 3-3. Examination of the NASN data by individual sites shows that the highest arsenic levels are consistently recorded in areas of Arizona, Montana, Tennessee, Texas, and Washington, which are impacted by the copper smelting industry. Thus, the closure of many of these plants for a substantial period in 1980 may have had the effect of depressing the nationwide average concentration of arsenic in ambient air for that year. Unfortunately, the possible effect of the 1980 copper smelter strike cannot explain the low arsenic levels observed in that year nationwide. Even urban areas in the Northeast, which would not be affected, exhibited lowered concentrations and the possibility that the analytical methodology may have systematically affected results cannot be ruled out.

Several factors of importance in assessing these data concern the partitioning of arsenic between particulate-bound fractions and vapor material as well as the lability of arsenic on air sampling filters. Non-particulate arsenic would chiefly be a problem in the immediate area of smelter emissions, adhesion to particulates increasing with residence time and distance from the emission source. Thompson (1976) has noted that all of the arsenic in the air in regions of smelters is adhered to particulates when sampled 2-3 kilometers from the operation. Lao et al. (1974) have cautioned about the hazard of arsenic loss, chiefly as the trioxide, from samplers at levels of 1.0 microgram or less. Walsh et al. (1977a), however, could not remobilize particulate arsenic once trapped in samplers. Whatever the hazard, the NASN values are internally consistent, remote areas having the lowest values and regions of smelter operations having the highest levels.

An important consideration in assessing the significance of air exposure of arsenic to health risk is the chemical form or forms of arsenic in the

ambient air of the United States. Work by Johnson and Braman (1975), as well as that of Attrep and Anirudhan (1977), indicates that methylated arsenic, possibly in significant amounts, has been found in air samples, but its presence can likely be ascribed to either biotic activity or the use of methylated arsenics as herbicides. This is not in total agreement with Andreae (1983), who suggests that methylated atmospheric arsenic is due predominantly to anthropogenic sources, based upon his studies of marine environments. Methylated forms become a minor factor in suburban and urban areas.

It is not clear from the available data what forms of inorganic arsenic are in most air samples: trivalent, pentavalent or mixtures of these two oxidation forms. Crecelius (1974) found that rain water samples for an urban area of the western U.S. contained only about one-third (35 percent) trivalent arsenic. In a study conducted at various sites along the Pacific coast, Andreae (1980) observed wide variations in the ratio of arsenite to arsenate in rain. He attributed this variability to emissions of predominantly pentavalent arsenic from the sea surface and trivalent arsenic from industrial emissions (particularly those from a copper smelter in the Northwest), and by redox reactions during the residence of arsenic in atmospheric particulates and hydrometeors. Caution should be exercised, however, in interpreting any extrapolations from washout samples to original air composition, given the lability of inorganic arsenic to oxidize or reduce depending on aeration, acidity of the rain sample, and presence of oxidizable matter.

In summary, then, one can assume that methylated arsenic is of minor concern in suburban and urban/industrial air samples, and that the major inorganic portion is a variable mixture of the trivalent and pentavalent forms.

REC 4954

TR 1639

3.3.2 Levels of Arsenic in Drinking Water

The National Interim Primary Drinking Water Regulations, promulgated under the Safe Drinking Water Act, set the Maximum Contaminant Level (MCL) for arsenic in U.S. public water supplies at 50 µg/l (40 CFR Part 141). EPA is currently reviewing the arsenic MCL as part of its program to promulgate National Revised Primary Drinking Water Regulations (EPA, 1983).

In general, arsenic is not found in drinking water at levels exceeding the MCL. The Community Water Supply Survey conducted in 1969 found only 2 of the 969 supplies examined (0.2 percent) with levels exceeding 50 µg/l (McCabe et al., 1970). More recently, the Rural Water Survey conducted in 1978 reported that 0.8 percent of rural households exceeded the 50 µg/l level. Small rural communities showed a much higher population (6.6 percent) of households exceeding 50 µg/l than large rural communities (0.0 percent) and other rural areas (0.4 percent). The proportion of households exceeding 50 µg/l was greatest in the West (2.1 percent) and North Central (1.8 percent); none were found to exceed 50 µg/l in the Northeast or South (Francis et al., 1982). Compliance monitoring of public water supplies as required by the current drinking water regulations has revealed that approximately 100 of the nation's 60,000 public water supplies (0.2 percent) have levels exceeding the current MCL (Wentworth, 1983).

Notable exceptions to the generally favorable picture for U.S. population exposure to drinking water arsenic are isolated well water sources associated with geochemical enrichment by arsenic found mainly in the western U.S. and Alaska (Arsenic. NAS, 1977; Whanger et al., 1977; Harrington et al., 1978; Southwick et al., 1981). Whanger et al. (1977) have noted that well water arsenic levels in Lane County, Oregon, have ranged up to 2.2 ppm (one well) with levels generally increasing with well depth. Harrington et al. (1978) also noted that an area of Fairbanks, Alaska, had well water levels

REC 4955

TR 1640

ranging as high as 10 ppm, representing geochemical input as well as contamination by residues from prior gold-mining activity. Southwick et al. (1981) reported levels ranging from 0.18-0.27 ppm in desert communities in Utah.

As with arsenic in air, it is important to take into account available information regarding the chemical forms of arsenic in the potable water supplies. It is reasonable to assume that the chief form of arsenic in most municipal water supplies, particularly surface reservoirs, would be pentavalent arsenic due to aeration and chlorination. Similarly, the major forms of arsenic in well waters relatively enriched in arsenic have been analyzed and also appear to be predominantly in the pentavalent inorganic state (Whanger et al., 1977; Harrington et al., 1978; Southwick et al., 1981). The chemical character of arsenic-rich well water in the U.S. versus other regions of the world will be taken up elsewhere.

3.3.3 Arsenic in Food

Perhaps the most useful body of data for assessment of the contribution of food arsenic to the total exposure picture in the U.S. is the recent survey carried out from August 1975 to July 1976 by the U.S. Food and Drug Administration (Johnson et al., 1981a,b). In Table 3-4 are summarized the average arsenic levels in various adult food classes for the period noted above; values are expressed analytically as arsenic trioxide. Corresponding average arsenic levels in food classes of 6-month-old infants and 2-year-old toddlers are summarized in Table 3-5.

In comparing the mean levels in comparable food categories, it appears that for children and adults, meat, fish, and poultry constitute the greatest dietary source of arsenic. Within this category, shellfish and other marine foods contain the highest levels of arsenic (Jelenik and Corneliussen, 1977). For infants, grain and cereal products constitute the only known source of arsenic intake from the categories measured.

Source: Adapted from Johnson et al. (1981a).

Johnson et al. (1981a) have calculated that the total adult daily intake of arsenic (as As_2O_3) for August 1975 to July 1976 was approximately 65 µg. (Corresponding elemental content can be obtained by multiplying by 0.75. Thus, the intake of elemental arsenic would be 50 µg.) This represents an increase over the 1974 value of 21 µg reported by Jelenik and Corneliussen (1977). Differences in the two years can primarily be accounted for by increases in the arsenic content of meat, fish, and poultry; grains and cereal products; beverages; and dairy products. Johnson et al. (1981a) did not discuss whether the apparent increase in arsenic levels in certain categories represented a trend or merely reflected analytical variation from year to year. It should be noted, however, that arsenic mean levels in all food categories generally declined over the years 1967-1974. Therefore, data collected over the past few years (1977-present) but, as yet, unanalyzed, should be closely examined in order to determine whether the increases seen in 1975-1976 have actually constituted the beginning of a new trend.

In no other medium is the issue of chemical forms of arsenic more complex and simultaneously more important than in food, given the fact that the diet is a major, if not the main, source of arsenic for most of the U.S. population. As will be pointed out in a later section, arsenic in crustaceans and other marine life is present in the form of various chemically complex organoarsenicals, which appear to be not only resistant to metabolism but are rapidly excreted intact. Comparatively speaking, then, these forms are regarded as being toxicologically inert.

3.3.4 Arsenic in Soils

Soil arsenic levels are mainly of concern in this section to the extent that arsenic mobility and transformation in this medium allow for passage of the element to ground water, air and the food chain (via plant uptake). This

REC 4959

TR 1644

area has been reviewed in some detail (Arsenic. NAS, 1977; Woolson, 1977; Walsh et al., 1977b).

Background levels of arsenic in soils range from less than 1 ppm to above 40 ppm, and the relative enrichment of this background level with agricultural practices is secondary to fallout from air in the regions of industrial activity and can be of the order of 100 times. In Table 3-6 are listed some comparative values for uncontaminated soils versus soils contaminated by the repeated use of defoliants and insecticides containing arsenic (Walsh and Keeney, 1975).

Arsenic in soils is usually bound to clay surfaces containing amorphous aluminum or iron oxides, the degree of immobilization (adsorption) being a function of soil type, soil pH, phosphate levels, levels of iron or aluminum as well as residence in soil. Soil-adsorbed arsenic is rather inert to transformation or movement and it is the soluble fraction which is of interest, usually in the pentavalent form. Pentavalent arsenic arises from both soil aeration and degradation of methylated arsenic herbicides. Little reductive methylation of arsenic occurs in typical soils compared to sediments, Woolson (1976) observing that only 1-2 percent conversion of arsenate occurred over a period of months.

Transfer of soil arsenic to plants entails the soluble, labile fraction of arsenic and the site of uptake is the root system where highest levels are found. Edible portions of most food plant classes are low. This is also the case for terrestrial flora, but marine plant life such as algae accumulates considerable levels of arsenic (Irgolic et al., 1977).

3.3.5 Other Sources of Arsenic

Small and McCants (1962) found an average of 1.5 ppm arsenic in tobacco residues taken from U.S. tobacco grown in soils having average arsenic levels

REC 4961

TR 1646

of 3 ppm. Of the total arsenic content of cigarette tobacco, 10-15 percent is in mainstream smoke (Thomas and Collier, 1945) in an unidentified form. In the past, levels of up to 40 ppm arsenic were detected in U.S. cigarettes (Holland and Acevedo, 1966) owing to arsenical use as pesticides. Lower current levels probably reflect curtailed use of arsenic as a pesticide in tobacco growing.

While current levels of arsenic may be lower in tobacco than had been the case, past exposure of cigarette smokers remains a health factor in considering respiratory cancer risk, given the long clinical induction period (decades) for this health effect (see Chapter 7).

REC 4962

TR 1647

4. ARSENIC METABOLISM

4.1 ROUTES OF ARSENIC ABSORPTION

The significance of various routes of arsenical intake for man and various other animal species is dependent upon the physical and chemical form of the arsenical, the mode of exposure, and the animal species under study. The major routes that are of significance to general public health are inhalation and ingestion, either via direct intake of food and water or secondary intake via the inhalation of arsenic in a form and size where it is eventually swallowed. Inhalation is probably of more significance in occupational settings, while oral intake is the major exposure route for the population at large.

Percutaneous absorption of arsenic, while poorly studied, appears to be a relatively minor route of exposure except under certain occupational exposure conditions.

4.1.1 Respiratory Absorption

Some quantitative and qualitative information about the respiratory deposition and absorption of arsenic by human subjects has been reported. Holland and co-workers (1959) used a group of hospital patients (lung cancer) to assess the deposition and absorption of inhaled arsenic using arsenite-containing cigarettes labeled with arsenic-74 as well as arsenite-containing aerosols. Deposition amounted to approximately 40 percent and more than three-fourths (75 to 85 percent) of the deposited arsenic was absorbed from the lungs within 4 days. While it may be argued that the health status of these subjects may have influenced the extent of absorption, it is nevertheless reasonable to infer that relatively rapid and extensive absorption of arsenic from the human lung likely occurs.

REC 4963

TR 1648

A study of a group of workers (Pinto et al., 1976) exposed to airborne arsenic in a copper smelter in 5-day test periods demonstrated average urinary arsenic excretion values ranging from 38 to 539 μg/liter to be associated with averages of air levels of arsenic ranging from 3 to 295 $\mu g/m^3$ (overall 53 μg As/m^3). Urinary arsenic was correlated with workplace air exposure (0.53, $p < 0.01$). Either direct pulmonary absorption or swallowing of larger particulate matter was evident as seen from elevations of urinary arsenic within 24 hours.

In a later study of copper smelter workers in which urinary excretion of arsenic was determined as total levels and chemically variant forms, Smith et al. (1977) studied control subjects and individuals from low, medium, and high arsenic exposure groups. In that study, the variations in concentrations of all arsenic forms isolated in urine--trivalent, pentavalent, methyl, and dimethylarsenic--were directly correlated with levels of airborne exposure (the relevant issue of arsenic biotransformation in vivo being discussed elsewhere in this chapter). An important feature of the Smith et al. (1977) report was the observation of a difference in the tightness of the correlation between excretion and exposure as a function of particle size. Both smaller, clearly respirable (<5 μm) and larger, less respirable (>5 μm) arsenic particles correlated well with excretion levels, but the less respirable arsenic-excretion relationship was seen to be much stronger than that for the finer mode particles. According to the authors, this is due to the swallowing of the large particle fraction and significant absorption from the GI tract.

Some animal data have also been reported on arsenic absorption via the respiratory tract. Bencko and Symon (1970) observed that hairless mice breathing a solid aerosol of fly ash containing 180 μg As/m^3 for several weeks had

REC 4964

TR 1649

increases in tissue arsenic values. Since the particle size was determined to be only less than 10 μm, part of this intake may have occurred via the GI tract. Increases in tissue arsenic in two exposure groups also occurred when rats were exposed to arsenic trioxide (condensation aerosols: 1.0, 3.7, and 46 $\mu g/m^3$) for 90 days (Rozenshtein, 1970).

Relatively rapid absorption of pentavalent arsenic (arsenate solution) was noted by Dutkiewicz (1977) when rats were exposed intratracheally (arsenate solution labeled with arsenic-74; 0.1 and 4.0 mg/kg). Arsenic tissue distribution dynamics were similar for intratracheal and companion intravenous exposure studies, indicating that the rate of intratracheal arsenic uptake more closely resembles that from parenteral administration than do oral or percutaneous exposures.

The pulmonary retention of arsenic compounds with different solubilities has recently been studied by two research groups.

Inamasu et al. (1982) gave 61 male Wistar rats single intratracheal instillations of arsenic trioxide or calcium arsenate suspended in phosphate buffer (pH 6.9). Controls (19) were given instillations of the phosphate buffer solution. The total dose of arsenic administered to each animal was about 2 mg in 0.2 ml suspensions.

Four to five of the arsenic-exposed animals were killed at intervals from 15 minutes to 168 hours after instillation. The average amounts of arsenic recovered in lungs of rats at 15 minutes after the instillation of calcium arsenate and arsenic trioxide were 1146 μg and 620 μg, respectively. After 24 hours, almost all of the deposited arsenic trioxide had disappeared from the lungs, whereas only about 50 percent of the calcium arsenate had been cleared as shown in Figure 4-1.

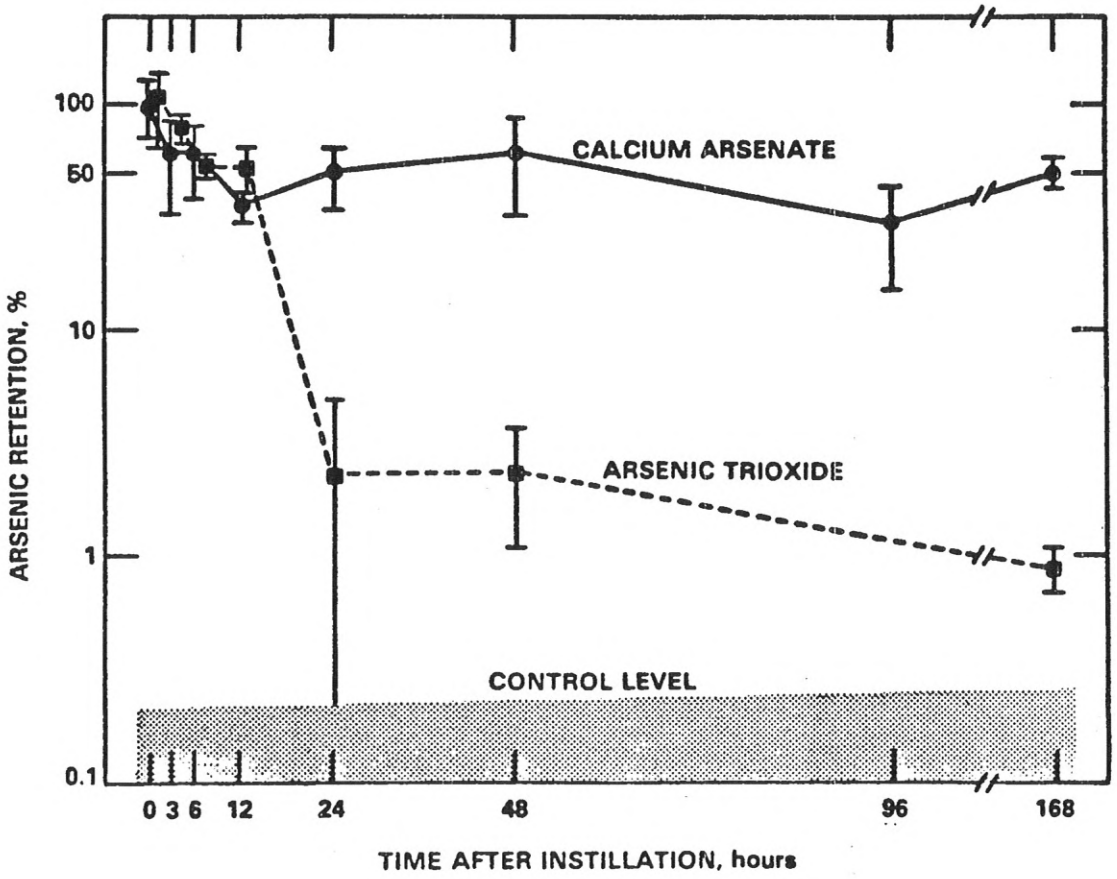

Figure 4-1. Arsenic retention in rat lungs following intratracheal instillation of a single dose. Percentage values are based on the average amount of arsenic present in rat lungs at 15 minutes after instillation of arsenic trioxide (- ■ -) or calcium arsenate (—●—). Vertical bars: means ± S.D.

Source: Inamasu et al. (1982).

Of the small remaining amount of arsenic trioxide, most gradually disappeared over the next several days, declining to a level of 5.6 µg at 168 hours after instillation, a level slightly higher than that seen in the controls (1.3 µg). In contrast, calcium arsenate remained at about the same level 168 hours after instillation as was observed after 24 hours (768 µg), clearly demonstrating a much higher level of retention compared to arsenic trioxide.

In the study by Pershagen et al. (1982), male Syrian golden hamsters were given four weekly intratracheal instillations of suspensions of arsenic trioxide, arsenic trisulfide and calcium arsenate in doses of 0.3, 0.5 and 0.5 mg arsenic, respectively. The suspensions were made in 0.9 percent NaCl, and sulfuric acid was added accordingly to equalize the acidity of the three different suspensions. Twenty animals were assigned to each treatment group. Five animals in each group were killed immediately after the first instillation. Two to five animals were then killed one week after two or four instillations and two weeks after four instillations.

The mortality was highest among the animals exposed to arsenic trioxide. In this group, 9 of the remaining 11 animals not sacrificed for tissue analysis had died by the week following the third instillation. In contrast, at the second instillation, two animals died in the group receiving arsenic trisulfide but no further deaths occurred in this group. A total of three animals receiving calcium arsenate died during the first week following the fourth instillation. Aside from those animals specifically sacrificed for tissue analysis, no other deaths occurred in this group either.

In the lungs, the amounts of arsenic were 386, 755 and 866 mg/kg wet weight immediately following instillation of arsenic trioxide, arsenic sulfide and calcium arsenate, respectively. One week after the second instillation

the amounts were 0.81, 9.2 and 579 mg/kg, respectively. In Figure 4-2 it can be seen that after the fourth instillation the differences between arsenate-exposed animals and the other groups were even more pronounced. Examination of the lungs revealed severe lung damage only among animals exposed to calcium arsenate. In all groups, areas with epithelial hyperplasia and metaplasia were seen.

Although different species and different time intervals were used in the above studies, the results were very consistent, i.e. arsenic trioxide was rapidly cleared from the lungs, whereas calcium arsenate was very slowly eliminated. The differences appear to be related to the relative solubility of the compounds, calcium arsenate having the lowest solubility. The doses in these two experiments were of the same magnitude, but the lung damage reported by Pershagen et al. among the arsenate-exposed animals might have influenced the clearance mechanisms. In addition, the possibility of higher acidity in the suspensions used by Pershagen et al. may also have had an influence.

The large differences in retention of arsenic compounds demonstrated in these two studies are of great interest in relation to the association between airborne arsenic and lung cancer. These differences in retention might explain the relatively high concentration of arsenic found in deceased smelter workers whose last exposure to arsenic occurred many years prior to death (Brune et al., 1980) (see Section 4.4). These workers were thought to be exposed to arsenic trioxide, but it may be that the retained fraction noted in the lungs was another arsenic compound of less solubility.

4.1.2 Gastrointestinal Absorption

In both man and experimental animals, factors which govern the absorption of arsenic from the gastrointestinal tract include the chemical form of the element, its physical characteristics, and dosing level. It can be stated

REC 4968

TR 1653

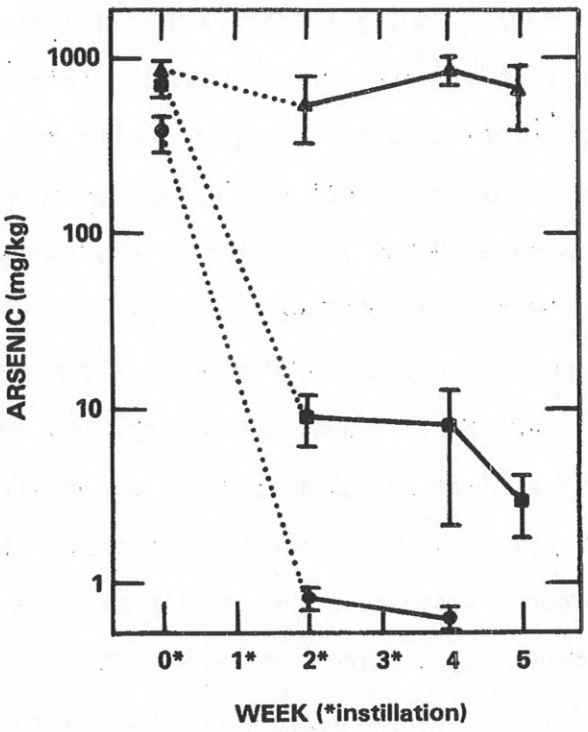

Figure 4-2. Lung concentrations of arsenic in hamsters given weekly intratracheal instillations of arsenic trioxide (●), arsenic trisulfide (■), or calcium arsenate (▲) (bars indicate ±1 S.D.). Animals at Week 0 were killed immediately following the first instillation; other animals were killed either 1 or 2 weeks after an instillation.

Source: Pershagen et al. (1982).

that soluble arsenicals will be generally more extensively absorbed than the insoluble forms. On the other hand, one should be cautious in extending correlations of simple water solubility to the chemical milieu existing in the GI tracts of various species.

Taken collectively, the reports of Coulson et al. (1935), Ray-Bettley and O'Shea (1975), Crecelius (1977), Mappes (1977), and Buchet et al. (1981a,b) demonstrate that very substantial absorption of soluble inorganic trivalent arsenic from the GI tract into the bloodstream typically occurs. Greater than 95 percent of inorganic arsenic taken orally by man appears to be absorbed, with less than 5 percent of the administered amount appearing in feces (Coulson et al., 1935; Ray-Bettley and O'Shea, 1975).

Consistent with the above observations, Mappes (1977) observed that daily oral intake of an aqueous solution of around 0.8 mg trivalent arsenic resulted in a daily urinary excretion of 69 to 72 percent of the daily dose in one subject. Also, Crecelius (1977) reported that ingestion of 50 µg trivalent and 13 µg pentavalent inorganic arsenic in a wine sample led to the appearance of 80 percent of all the ingested arsenic in urine within 61 hours. Crecelius (1977), however, reported that ingestion of well water mainly containing identified pentavalent inorganic arsenic led to urinary clearance of half the intake within approximately 3 days.

More recently, Buchet et al. (1981b) found that daily arsenic excretion via urine in human volunteers exposed to the dose range 125-1000 µg/day amounted to 60 percent of the dose. Steady state was achieved within 5 days after arsenic dosing began.

In contrast to the relatively high absorptive rate for soluble inorganic arsenic, Mappes (1977) reported that insoluble arsenic triselenide (As_2Se_3), when taken orally, passes through the GI tract with negligible absorption.

REC 4970

TR 1655

Arsenic intake via the diet of non-occupationally exposed populations requires that one consider the issue of bioavailability. Arsenic in foodstuffs is probably incorporated into the matrix of these commodities in a variety of ways.

The "shrimp" arsenic present in crustaceans and other fish appears to represent a complex organic form of the element which has prompted considerable recent study (LeBlanc and Jackson, 1973; Westöö and Rydälv, 1972; Munro, 1976; Edmonds et al., 1977; Penrose et al., 1977; Crecelius, 1977; Edmonds and Francesconi, 1977). In brief, the results of such studies indicate that the arsenic present in shellfish and other marine foods appears to be extensively absorbed and rapidly excreted intact as a complex organoarsenical by man and animals, and, as such, does not appear to pose a particular health threat to man.

Studies of the oral intake and absorption of arsenicals in experimental animals have also been conducted and generally confirm the findings derived from the above human studies. More specifically, soluble inorganic arsenic, delivered as either trivalent or pentavalent solutions, is almost completely absorbed from the GI tract of rats (Coulson et al., 1935), with 88 percent absorption being observed for arsenic trioxide solution (Urakabo et al., 1975; Dutkiewicz, 1977) and 70 to 90 percent for arsenate solution. Similar observations have been made for pigs (Munro et al., 1974), with 90 percent of arsenic trioxide solution being absorbed, and monkeys (Charbonneau et al., 1978a), with 98 percent of arsenic trioxide being absorbed. Also, Charbonneau et al. (1978b) fed arsenic-containing fish (Atlantic grey sole) to adult female monkeys as a homogenate (1 mg fish arsenic/kg body weight) and noted that about 90 percent of the intake was absorbed, of which about 75 percent appeared in urine after 14 days. In a related study, swine and adolescent

monkeys were seen to absorb approximately 70 and 50 percent, respectively. On the other hand, arsenic trioxide in suspension given orally to rabbits and rats was reported to result in only about 40 and 30 percent absorption, respectively (Ariyoshi and Ikeda, 1974).

4.1.3 Transplacental Passage

Potential fetal exposure to toxic elements via the mother is a matter of major importance given the potential sensitivity of *in utero* development to deleterious impacts of exogenous toxic agents.

In an arsenic-detection study of maternal-newborn blood groups, Kagey et al. (1977) reported that cord blood levels approximated those of mothers in 101 subject sets. Tissue analysis (Kadowaki, 1960) of fetus arsenic in a presumably healthy Japanese population indicated measurable element levels by at least month four of gestation which increased to month seven. Of importance in this study was the observation that brain levels, as well as those of bone, liver, and skin, were the highest of all tissue tested.

Complicating the issue is the chemical nature of the tissue arsenic assayed in either of the two studies noted above, inasmuch as precise chemical speciation was not attempted. Also, the Japanese study presumably did not select material in a manner such that dietary histories could be discerned. Thus, questions can be raised regarding implications of these data for fetotoxicity.

Transplacental transfer of arsenic has also been demonstrated in experimental animals. Transplacental transfer of arsenate administered parenterally in hamsters has been demonstrated by Ferm's laboratory (Ferm, 1977; Hanlon and Ferm, 1977). The movement was rapid, with embryonic tissues showing levels close to those in maternal blood 24 hours after dosing. Trivalent arsenic exposure results in transplacental passage in pregnant rats. Arsenic was detected in newborn rats when the dams received arsenic trioxide in their diets.

4.2 BIOTRANSFORMATION PROCESSES IN VIVO

An understanding of the metabolism of inorganic arsenic by man and a number of other species is substantially complicated by a series of newly-revealed biotransformations, including methylation of inorganic arsenic. It is thus appropriate to discuss *in vivo* transformation processes at this point, since many of the data dealing with blood transport, tissue distribution and subsequent excretion are much better understood in light of these findings.

A major factor in the determination of transformation processes for arsenic in man and other animals was the evolution of appropriate analytical methods within the decade which permit chemical speciation of chemically variant forms of arsenic with reference to both oxidation-state lability and inorganic versus organo-substituted arsenic.

These procedures involve different analytical approaches and include selective reduction of various arsenic forms to the hydride, and subsequent analysis by colorimetry (Lakso et al., 1979), emission spectrometry (Braman and Foreback, 1973; Crecelius, 1977), atomic absorption spectrometry (Edmonds and Francesconi, 1977; Buchet et al., 1980), and gas-liquid chromatography (Andreae, 1977; Talmi and Bostick, 1975). Alternatively, inorganic arsenic (III) or (V) and methylated forms can be directly measured by ion-exchange chromatographic techniques (Tam et al., 1978; Henry and Thorpe, 1980).

There are a number of points germane to consideration of *in vivo* transformations of arsenic: 1) biomethylation of inorganic arsenic; 2) oxidation-reduction of inorganic arsenic *in vivo*; 3) the relative chemical stability of inorganic arsenic to oxidation-reduction as it affects experimental dosing and chemical speciation in biological media.

4.2.1 Biomethylation of Inorganic Arsenic in Humans and Experimental Animals

An extensive literature has recently appeared documenting the *in vivo* methylation of inorganic arsenic to monomethyl and dimethyl arsenic (the latter

REC 4973

TR 1658

being the major methylated metabolite) in every mammalian system studied to date, including man.

While the quantitative features of this phenomenon may vary among species, one can generally state that: 1) dimethyl arsenic is the major transformation product in both humans and animals, with higher amounts of monomethyl arsenic, when formed, found in humans; 2) methylation is assumed to be a route of detoxification of the more toxic inorganic forms; 3) dimethyl arsenic appears to be a terminal metabolite, formed relatively rapidly and rapidly excreted; 4) while the in vivo methylating capacity of a given system may persist over a range of inorganic arsenic exposure, at some point the body burden of the unmethylated fraction is enough to induce toxic effects, evidenced by the extensive literature dealing with inorganic arsenic toxicity; 5) retrospective assessment of earlier data dealing with arsenic metabolism, including distribution and excretion, must be viewed in light of current knowledge about biomethylation in different species; and 6) biomethylation appears to be a reductive process involving step-wise arsenic reduction and methyl transfer steps.

4.2.1.1 Human Studies--Using a method that permits the determination of tri- and pentavalent inorganic arsenic as well as mono- and dimethylarsenic acids via selective reduction, volatilization, and helium-arc emission detection, Braman and Foreback (1973) analyzed the urinary excretion of arsenic in four human subjects. About 66 percent of the total urine arsenic concentration (22.5 ppb) was present as dimethylarsinic acid and 17 percent as pentavalent inorganic arsenic. Trivalent inorganic arsenic and methylarsonic acid were present in equal amount, approximately eight percent each.

Crecelius (1977) reported the urinary excretion of form-variable arsenic when a human subject ingested arsenic-rich wine (50 µg trivalent and 13 µg pentavalent). About 80 percent of the arsenic ingested with the wine was

REC 4974

TR 1659

excreted within 61 hours. Of the total excreted, 63 percent was in the form of dimethylarsenic acid, 18 percent was monomethyl arsenic acid, and approximately 9 percent each was in the two inorganic forms.

Consumption of well water containing 200 µg of arsenate by a subject in the same study showed urinary trivalent arsenic at near background levels with an elevation in pentavalent form as well as significant excretion of dimethylarsenic. Of the total amount ingested, about 50 percent was recovered in urine by 3 days. Arsenic as contained in canned crab tissue was also studied in this experiment. It has been established that arsenic is present in marine foods in an organic form which is excreted intact.

The study of Smith et al. (1977), using basically the same speciation/analysis techniques noted in the previous study and involving urinary profiles for a group of copper smelter workers, also confirmed transformation processes in vivo. In controls, as well as in three study groups that varied as to intensity of airborne trivalent arsenic oxide exposure, dimethyl arsenic was the dominant species in urine, followed by methyl arsenic, trivalent arsenic and pentavalent arsenic, in descending order.

In another smelter worker study, Buchet et al. (1980) assessed the distribution of arsenic and metabolites in urine samples in different groups according to the degree of inorganic arsenic exposure. Total urinary arsenic in exposure groups ranged from 74 to 934 µg/liter, of which 75 percent represented methylated forms (mono- and dimethyl), with dimethyl arsenic predominating. Control subjects showed a somewhat higher level of methylated arsenic in urine, approximately 90 percent, suggesting some dependency of the extent of methylation on the level of exposure.

A number of recent studies have described in more detail the biomethylation of inorganic arsenic using human volunteers.

Buchet et al. (1981a) followed the urinary excretion of inorganic and methylated arsenic in 3-5 volunteers ingesting single amounts of arsenic at a dose of 500 µg, in the form of either arsenite, monomethyl or dimethyl arsenic. After 96 hours, 46 percent of the dose in subjects given arsenite (trivalent arsenic) was excreted, 25 percent in the inorganic form and 75 percent as methylated metabolites. Of the latter, one-third was monomethyl arsenic and two-thirds was the dimethylated form. Dimethyl arsenic was excreted intact, 75 percent of the ingested amount appearing in urine by 96 hours. With monomethyl arsenic, excretion reached 80 percent by 96 hours, with around 13 percent of the urine level representing conversion to the dimethyl form.

In a follow-up report, these workers (Buchet et al., 1981b) monitored the urinary excretion of various arsenical forms in 4 human subjects undergoing repeated ingestion (5 days) of trivalent inorganic arsenic as a meta arsenite salt at 4 levels--125, 250, 500 or 1000 µg As. By 14 days, the percent of methylated forms of total forms ranged from 74-93 percent over the intake range. From this study, it would appear that the methylating capacity of the human subject was unaffected up to the 500-µg As level, at which point some decrease in methylated arsenic as a percentage of total was observed.

Yamauchi and Yamamura (1979) reported their results with 3 volunteer subjects who ingested an arsenic-rich extract (prepared from a particular kind of seaweed) containing 2.88 ppm total arsenic. Of the total amount, 86 percent was pentavalent inorganic arsenic, 7 percent was trivalent inorganic arsenic and 7 percent was dimethyl arsenic. These volunteers ingested the preparation as a single dose at a level of 10 µg/kg body weight, for total amounts of 650, 680, and 760 µg in the three subjects. By 48 hours, urine levels of total arsenic amounted to 36 percent of the dose. Of the excreted amount, dimethyl and monomethyl arsenic accounted for 47.4 and 25.3 percent, respectively.

REC 4976

TR 1681

4.2.1.2 Animal Studies--To date, biomethylation processes involving inorganic arsenic and experimental animals have been documented in dogs (Lakso and Peoples, 1975; Charbonneau et al., 1978a; Tam et al., 1979a), mice (Vahter, 1981), rabbits (Marafante et al., 1980; Bertolero et al., 1981), the bovine (Lakso and Peoples, 1975), and the rat (Odanaka et al., 1978). While the level of methylated forms of arsenic in most experimental species resembles that in man, approximately 80 percent, there is a greater amount of the dimethyl and a lesser amount of monomethyl arsenic.

Vahter (1981) has shown: (1) that the degree of biomethylation is dose-dependent, at least in mice, falling off in relative percentage with increasing level of dosing; (2) that this dependency probably accounts for the observation of dose-dependent retention in mice; and (3) methylation occurs to a greater extent with trivalent arsenic than with the pentavalent form, although retention, relative to total dose, is greater with the trivalent form.

Recently, Vahter et al. (1982) have reported that the Marmoset monkey, alone among all mammalian experimental species studied thus far, does not methylate inorganic arsenic.

4.2.2 In Vivo Oxidation/Reduction of Inorganic Arsenic In Mammalian Systems

From all available evidence, the biochemical mechanism of *in vivo* methylation of inorganic arsenic appears to be a reductive process, and sequential arsenic reduction and transmethylation steps in the pathway have been documented in microbial systems (Challenger, 1978; McBride et al., 1978). In mammalian systems, recent studies support a similar reduction/methylation sequence as observed in microflora.

Oxidation of trivalent inorganic arsenic to the pentavalent state has been claimed in dogs (Ginsberg, 1965), rats (Winkler, 1962), mice (Bencko et al., 1976), and humans (Mealey et al., 1959). An important factor in considering these studies critically is the fact that none of the reports considered

the presence of methylated arsenic, which may well have affected the analytical techniques employed and the analytical data obtained. Secondly, except for the Bencko et al. (1976) study, it is not clear that careful attention was paid to the oxidation state composition of dosing media or the effect of sample handling on oxidation state stability. In the Mealey et al. (1959) report, the analytical method involved acidification of urine with hydrochloric acid and extraction of the presumed "trivalent" arsenic into benzene, leaving the presumed "pentavalent" form in the aqueous phase. Since Mushak et al. (1977) have shown that methylarsonic and dimethylarsinic (cacodylic) acid behave like the pentavalent inorganic form in this extraction procedure, it is probable that the "arsenate" fraction was mainly methylated arsenic.

In the study of Crecelius (1977), where chemical speciation techniques were employed, it does not appear that ingestion of a sample containing mainly arsenite (trivalent form) is associated with excretion of pentavalent inorganic arsenic as the chief inorganic form. After 61 hours, 80 percent of the ingested amount appeared in urine, with the two inorganic forms each constituting minor fractions, mono- and dimethyl arsenic being the main forms.

Evidence for the in vivo reduction of pentavalent to trivalent inorganic arsenic has been claimed in several early reports. Lanz et al. (1950) reported some reductive conversion (10-15 percent) of arsenate to arsenite in rats, using as a method the precipitation from urine of arsenate as a mixed salt and analysis of the supernatant for arsenic (III). The accuracy of this method for partitioning trace arsenic levels is questionable. Furthermore, at the time of this study, the presence of methylated arsenic was not known. Therefore, it is not possible to accept the authors' conclusions since unprecipitated arsenic could also have consisted of methylated forms.

Ginsberg (1965) reported that 14 percent of urinary and 6 percent of plasma arsenic in dogs receiving intravenous infusion of arsenate was in the

REC 4978

TR 1663

form of trivalent arsenic. In this study, trivalent was presumably separated from pentavalent arsenic by chelation-extraction using ethyl xanthate. Based on current knowledge that methylated arsenic was present, it is difficult to accept the data without knowledge of the behavior of mono- and dimethyl arsenic in this analytical method.

In the recent report of Tam et al. (1979b) using dogs dosed with arsenate, a small amount of trivalent inorganic arsenic was detected in urine, using ion-exchange and thin-layer chromatographic techniques. These authors did not independently determine the extent of artifactive interconversion between the two forms using these techniques.

In a recent study by Vahter (1981), in which mice and rats were administered ^{74}As-labeled trivalent or pentavalent arsenic, the author reported that increases in retention with dose were less pronounced for the pentavalent form than for the trivalent form due to the fact that elimination of pentavalent arsenic seemed to be less dependent on methylation. Nevertheless, increases in retention with pentavalent arsenic were observed. Vahter discussed the possibility that the observed dose-related increase in retention after exposure to pentavalent arsenic may have been partly due to *in vivo* reduction of the pentavalent to trivalent form. Noting the work of McBride et al. (1978), whose studies indicated that certain microorganisms required reduction of pentavalent arsenic to trivalent before methylation could proceed, Vahter suggested that a similar mechanism might have been functioning in both the mice and rats. Evidence to support this hypothesis was presented in the author's observation that trivalent arsenic seemed more readily methylated than pentavalent.

Two recent studies, carefully designed for the specific purpose of addressing the oxidation/reduction issue for inorganic arsenic *in vivo*, have demonstrated that pentavalent arsenic (arsenate) undergoes reduction *in vivo* to

the trivalent state in the rat (Rowland and Davies, 1982) as well as in mice and rabbits (Vahter and Envall, 1983). In both of these investigations, the issue of artifactual interconversion of these two valence states was carefully addressed.

In the rat (Rowland and Davies, 1982), administration of moderate doses of pentavalent arsenic led to rapid reduction to the trivalent form. In mice and rabbits, the rate of conversion was somewhat slower than in the rat, but still occurred at a significant rate. Trivalent arsenic was measured in arsenate-dosed mice plasma by 1 hour post-dosing.

In a summary report, Peoples (1983) reported, without experimental detail, that the feeding of sawdust containing chromated copper arsenate did not result in measurable urinary levels of trivalent arsenic. Since these animals were exposed to copper as well as chromium (VI), in addition to arsenate, it is difficult to differentiate any influence these agents may have had on the results. Peoples (1983) also noted that renal perfusion of dogs with a very dilute solution of arsenate did not lead to renal reduction of pentavalent to trivalent arsenic. In the absence of experimental details, it is not possible to determine what steps were taken to avoid artifactual conversion of trivalent back to pentavalent arsenic, if the lower valence form was indeed formed.

Studies by Lerman and Clarkson (1983) of penta- and trivalent arsenic in the rat are fully consistent with a reductive methylation process. Using in vivo and in vitro techniques, the authors showed that the isolated rat liver hepatocyte readily methylates trivalent arsenic, while virtually no conversion occurs with the pentavalent form, although it is known that pentavalent arsenic is also extensively methylated in vivo. These data suggest that arsenate must first be converted to arsenite elsewhere in the organism.

Two recent studies using human subjects and identical chemical speciation techniques for arsenic appear to offer conflicting data regarding pentavalent arsenic reduction.

Crecelius (1977) noted that ingestion, by a single subject, of a sample of well water tested as having 200 µg As only in the pentavalent form resulted in a urinary level of trivalent arsenic which was virtually the same as background concentration before taking the arsenic sample. Although urine was collected for approximately 3 days, a significant amount of the total dose was unaccounted for, making it difficult to draw any conclusions from the study.

Yamauchi and Yamamura (1979) fed a preparation of seaweed containing 86 percent pentavalent arsenic and 7 percent each of trivalent inorganic and dimethyl arsenic to 3 human subjects as one dose at a total dosing of 650, 680, and 760 µg total arsenic. By 48 hours, based on their method which was the Braman et al. (1977) procedure, 36 percent of the original dose appeared in urine, with 75 percent present as methylated forms and about 17 percent present as trivalent arsenic (6.3 percent of the total amount ingested). The authors calculated that the amount of trivalent inorganic arsenic was greater than could be ascribed to the small amount ingested originally and they stated that the fraction represented in vivo reduction of pentavalent arsenic. Since the mean intake was approximately 700 µg, the 7 percent present as trivalent inorganic arsenic amounted to 49 µg, of which 36 percent or 18 µg would have been expected to appear in urine in some form. Using 75 percent methylation, only approximately 4-5 µg would have been present as the trivalent form, when in fact a mean value of 43.4 was found (range: 36-51 µg). Since the Braman et al. (1977) method is a reasonably accurate speciating technique and there is little evidence that samples were handled in a way to promote artifactive formation of trivalent arsenic after excretion, the data cannot be readily questioned on this basis.

4.2.3 Chemical Stability of Trivalent and Pentavalent Inorganic Arsenic to Oxidation-Reduction

In aerated water, trivalent inorganic arsenic will undergo extensive oxidation to the pentavalent form, particularly when present at low levels (Feldman, 1979).

The pH of aqueous solutions appears to be the major factor in the relative stability of either valency form. Buchet et al. (1980) found that trivalent arsenic in solutions at pH of 7.0 or 9.6 were oxidized to the extent of 70-90 percent within one week, compared to 25 percent conversion at pH 4.8.

Vahter and Norin (1980) also noted rapid oxidation of As (III) in aqueous solution at room temperature, while storage at 4°C showed little conversion.

Pentavalent inorganic arsenic, on the other hand, is stable at neutral or alkaline pH but undergoes reduction with decreasing pH (Durrant and Durrant, 1966).

In studies directed to *in vivo* transformations of inorganic arsenic, urine levels are commonly used and some data exist regarding valency stability of arsenic in urine.

Buchet et al. (1980) found that trivalent inorganic arsenic in urine at pH 7.0 or less was relatively stable, with only 10 percent oxidation occurring by 7 days. At pH 9.5, 50 percent of oxidation occurred within one day.

4.3 DISTRIBUTION OF ARSENIC IN MAN AND ANIMALS

Blood is the main vehicle for transport of arsenicals from absorption sites to the tissues, with the hemokinetic character of arsenic being dependent on the animal species studied.

It is readily apparent from the literature that the rat constitutes an anomalous model for studies of the fate of inorganic arsenicals *in vivo* and this includes the clearance behavior of rat blood-borne arsenic (Hunter et al., 1942; Ducoff et al., 1948; Lanz et al., 1950; Ariyoshi and Ikeda, 1974;

REC 4982

TR 1667

Klaassen, 1974; Tsutsumi and Kato, 1975; Dutkiewicz, 1977). In the case of the rat, arsenic in blood is only slowly cleared following exposure, with about 80 percent of the total blood arsenic content localized in the erythrocyte. The half-times of blood clearance for inorganic arsenic in the rat (trivalent or pentavalent) is on the order of 60 to 90 days (Lanz et al., 1950; Ariyoshi and Ikeda, 1974).

Arsenic in the blood of other species--man (Ducoff et al., 1948; Mealey et al., 1959; Tam et al., 1979b), mice (Lanz et al., 1950; Crema, 1955), rabbit (Hunter et al., 1942; Ducoff, 1948; Klaassen, 1974), dog (Lanz et al., 1950; Hunter et al., 1942), and primates (Hunter et al., 1942; Klaassen, 1974)--whether given as the pentavalent form or as the trivalent form, is rapidly cleared. Normal blood arsenic values for individuals in the U.S. and Europe are in the range of 1-5 µg total arsenic/liter whole blood (Bergstromn and Wester, 1969; Damsgaard et al., 1973; Kagey et al., 1977; and Valentine et al., 1979). According to Kagey et al. (1977), cigarette smokers showed mean blood arsenic levels approximately 50 percent higher than nonsmokers. It is reasonable to assume that human background blood levels reflect mainly dietary arsenic, much of which would likely be in various organo-arsenical forms that are extensively absorbed and rapidly cleared.

Clearance of arsenic in dog and man was found to fit a three-compartment model by Charbonneau et al. (1978a) and Tam et al. (1979b) with half-times of 1, 5, and 35 hours, respectively. When contrasted with the work of Tam et al. (1978), which reported the time-dependent in vivo methylation of arsenic and excretion in dogs, the various components presumably relate to initial excretion of inorganic arsenic, followed by clearance of dimethyl arsenic.

The tissue partitioning of arsenic in man has been studied using both autopsy and dosing data. Kadowaki (1960) found (measurements in ppm, wet

REC 4983

TR 1668

weight) that nails (0.89), hair (0.18), bone (0.07-0.12), teeth (0.08) and skin (0.06) generally housed the highest absolute amounts of arsenic, while heart, kidney, liver and lung contained somewhat lower levels (0.04-0.05). Brain tissue (0.03) had an arsenic level only slightly lower than other soft tissues. Liebscher and Smith (1968), analyzing tissue samples (ppm dry weight) from non-exposed sources in Scotland, observed lung to have the highest levels (0.09), with liver and kidney levels (0.03) not materially different from other soft tissue. Like the Kadowaki study, hair (0.46), nails (0.28) and skin (0.08) had the highest absolute values; however, bone and teeth (0.05) did not contain levels appreciably different from some other tissues (pectoral muscles, 0.06; ovary, 0.05; and pancreas, 0.05).

In addition to the autopsy studies by Kadowaki (1960) and Liebscher and Smith (1968), Larsen et al. (1979) have recently reported on a detailed study of the topographical distribution of arsenic in normal human brain tissue. Arsenic is distributed throughout all brain regions, with white matter showing higher levels than gray matter.

In looking at tissue distribution of arsenic in experimental animals, exposure of various species to either tri -or pentavalent arsenic leads to the initial accumulation of the element in liver, kidney, lung, spleen, aorta, and skin (Hunter et al., 1942; Ducoff et al., 1948; Lanz et al., 1950; Peoples, 1964; Ariyoshi and Ikeda, 1974; Cikrt and Bencko, 1974; Klaassen, 1974; Tsutsumi and Kato, 1975; Urakabo et al., 1975; Dutkiewicz, 1977; Sabbioni et al., 1979; Marafante et al., 1980). With the exception of the rat, a species in which metabolism of arsenic is only a very limited model for study of this element (vide supra), clearance from soft tissue is rather rapid except for the skin, where the high sulfhydryl group content may promote tight trivalent arsenical binding. As also seen with human tissue, arsenic is apparently lodged in

REC 4984

TR 1669

brain of experimental animals exposed to arsenic, with slow clearance reported (Crema, 1955).

Recently, Vahter and Norin (1980) compared the dependency of dose and valency form of inorganic arsenic on tissue compartmentalization of arsenic in mice. Unlike most of the earlier reports, these workers used chemical speciation techniques (ion-exchange chromatography) to verify that their dosing media contained purely tri- or pentavalent arsenic. Using single oral dosing at 0.4 or 4.0 mg/kg levels and radioisotopic tri- or pentavalent arsenic, levels of arsenic in kidney, liver, bile, brain, skeleton, skin and blood were always greater (2-10 fold) in terms of percent total dose for the trivalent form than for the pentavalent form, and most pronounced at the higher dose. These workers ascribe much of this difference to relative methylating efficiency as a function of exposure level and valence form.

In a similar study using Golden Hamsters exposed to injected tri- or pentavalent radioisotopic arsenic, with care taken to assure valence purity, Ckirt et al. (1980) found that levels of arsenic in liver, kidneys, gut wall and bile were always greater, 2 to 25-fold, with trivalent arsenic exposure.

4.4 ARSENIC ACCUMULATION

The long-held view of arsenic as an element that accumulates in the body was mainly based on the behavior of arsenic in the rat, an animal model which in retrospect was the least helpful in understanding the fate of the toxicant *in vivo* for other mammalian species and man.

Based on current arsenic elimination data for all mammalian species studied other than the rat (*vide supra*), one concludes that marked long-term accumulation of arsenic generally does not occur in physiologically vital components of the body. This is in contrast to, say, long-term lead accumulation in bone or cadmium accumulation in renal cortex. Autopsy tissue data for

REC 4985

TR 1670

human subjects of different ages are not conclusive regarding possible long-term tissue accumulation. Kadowaki (1960) did observe higher mean levels of arsenic in skin and kidney samples of subjects approximately 50 years of age versus infant values, but dietary histories of the subjects were not available to allow for differentiation of increases in arsenic levels due to current versus past exposures for the older subjects. Deposition in hair is really excretory in nature, not accumulative.

Brune et al. (1980) have reported that lung tissue from retired smelter workers from the Rönnskär smelter in Sweden, on autopsy, had median values for arsenic which were about 8 times higher than that for a control group. Kidney and liver values, however, were not significantly different between smelter worker groups and controls. Arsenic accumulation in the lung of smelter workers even after several years of retirement and removal from workplace exposure (interval of 2-19 years) suggests that a very insoluble form of arsenic exists in smelter ambient air and is inhaled by these workers.

Lindh et al. (1980) measured the arsenic in autopsy femur samples of 7 occupationally exposed workers. The time between retirement and death ranged from 0-21 years. A control sampling from 5 autopsy cases was included. Using both neutron activation analysis and proton-induced X-ray emission (PIXIE) techniques, no clear evidence of significant arsenic accumulation in bone was seen. The scatter of levels was wide in the worker group, 0.006-0.21 ppm, with a median of 0.014 ppm, versus a range of 0.005-0.007 ppm in the control samples.

4.5 ARSENIC EXCRETION IN MAN AND ANIMALS

Renal clearance appears to be the major route of excretion of absorbed arsenic in man and animals, biliary transport of the element leading to enteric reabsorption with little carriage in feces.

REC 4986

TR 1671

Recent data for normal or background levels of arsenic in urine of human subjects in the U.S. reveal values of less than 20 µg/liter (20 ppb). If seafood has been consumed, such values can rise considerably to levels of 1,000 µg/liter or higher (Westöö and Rydälv, 1972; Pinto, 1976).

In a study designed to assess the utility of urine arsenic measurement in occupational exposure settings, Mappes (1977) reported excretion data for both single and multiple daily dosing for a human subject ingesting an arsenite solution. By 3 hours, renal excretion was maximal, with about one-quarter of the single dose appearing in the urine by day 1 post-exposure. With successive arsenite ingestion (0.8 mg As), daily urinary clearance after 5 days was about two-thirds of daily intake.

Buchet et al. (1981b), in their study of human subjects ingesting arsenite in amounts ranging from 125-1000 µg/day for 5 days, calculated a steady state occurring within 5 days. With steady state, 60 percent of daily intake is excreted daily. This figure is in good agreement with that of Mappes (1977) cited above.

Crecelius (1977) noted that following ingestion of arsenic in wine [50 µg As (III), 13 µg As (V)], approximately 80 percent of the dose was excreted within 61 hours. Oral ingestion of arsenic (V) in well water (200 µg), however, led to about 50 percent urinary excretion by 3 days post-ingestion. Mealey et al. (1959) measured urine arsenic in patients given trivalent arsenic by intravenous administration, with approximately 60 percent of the dose amount appearing in the urine within 24 hours. Hunter et al. (1942) noted that a group of human subjects given arsenic via parenteral administration exhibited considerable variance in the urinary clearance of arsenic, ranging from 30 to 80 percent after 4 to 5 days.

As might be predicted from the in vivo behavior of arsenicals in the rat, urinary excretion of arsenic in this species is very slow (due to erythrocyte

REC 4987

TR 1672

retention) on the order of two to five percent of the arsenic intake by several days post-dosing (Coulson et al., 1935; Ariyoshi and Ikeda, 1974). Urakabo et al. (1975) calculated a half-time of 84 days for arsenic in the rat.

Slow clearance of arsenic from the rat gave rise to the widely-held assumption for many years that arsenic was one of the elements that accumulated in the body. Other species excrete arsenic rapidly. Mice, rabbits, swine, dogs, and monkeys clear the majority of injected trivalent arsenic within 24 hours, with excretion usually being $\geq$70 percent within that time period (Ducoff et al., 1948; Crema, 1955; Munro et al., 1974; Lakso and Peoples, 1975; Tam et al., 1978; Charbonneau et al., 1978a). Other studies also indicate rapid urinary clearance of arsenic given in the pentavalent form to species other than the rat (DuPont et al., 1942; Ginsberg and Lotspeich, 1963; Peoples, 1964; Lakso and Peoples, 1975).

Several studies have compared the relative rates of elimination of radiolabeled (^{74}As) trivalent and pentavalent inorganic arsenic (Vahter and Norin, 1980; Vahter, 1981) where precautions were taken to assure the purity of the respective dosing solutions as to valency state. Whole-body retention of trivalent inorganic arsenic in mice was 2-3 times greater than that of arsenate while retention times for both forms were dose-dependent, increasing with increasing exposure. In these studies, the animals received single oral doses of either form at levels of 0.04 to 4.0 mg As/kg. Differences in elimination rates appeared to relate to the relative degree of methylation of inorganic arsenic to the rapidly excreted methylated forms, chiefly dimethyl arsenic. Furthermore, differences in excretion rates were dose-dependent. At 0.04 mg As/kg, there was no difference between tri- and pentavalent arsenic elimination (Vahter, 1981).

Biliary transport of arsenic has been reported for a number of species. Bile-excreted arsenic is reabsorbed. Cikrt and Bencko (1974) noted that the

REC 4988

TR 1673

rat had a higher biliary excretion rate for the trivalent than for the pentavalent form (approximately 10:1). Klaassen (1974) noted that the biliary excretion rate was much greater for the rat than for either the rabbit or the dog.

Cikrt et al. (1980) monitored biliary exretion in the Golden Hamster using penta- or trivalent inorganic arsenic. Significant differences in biliary excretion rates and cumulative excretion were seen between the two forms, being much greater for the trivalent form. However, fecal and urine arsenic content were greater with pentavalent arsenic administration. Biliary transport data for man are not available.

Deposition of arsenic in such organs as hair and nails can be considered an excretory mechanism for arsenic. Although hair analysis has had a long history in the chemical and forensic arsenic literature, for reasons of both analytical convenience and the possibility of establishing an exposure history from sectional analysis, many questions remain unanswered. The relationship between arsenic deposition in hair and various exposure parameters has not been well defined on a quantitative basis, nor are the physiological mechanisms well understood. The chemical nature of hair arsenic is also largely unknown.

5. ARSENIC TOXICOLOGY

The acute and chronic toxicity of arsenic will largely depend on the chemical form and physical state of the compound involved. Inorganic trivalent arsenic is generally regarded as being more acutely toxic than inorganic pentavalent arsenic, which in turn is more toxic than methylated forms of arsenic (NAS, 1977; Pershagen and Vahter, 1979; WHO, 1981). The previously noted (Chapter 3) "fish arsenic" is regarded as nontoxic. It is thus necessary to always specify, if possible, arsenic compounds when discussing effects and constructing dose-effect and dose-response relationships. In addition, factors like particle size and solubility must be taken into account. Trivalent compounds with low solubility, e.g., arsenic sulfide, will have low oral toxicity but may be retained in the lung (Pershagen et al., 1982).

The following chapter discusses the non-mutagenic/non-carcinogenic effects of exposure to inorganic arsenic. Because of the large volume of information available regarding the mutagenic and carcinogenic effects of inorganic arsenic, these topics have been discussed in the following chapters.

5.1 ACUTE TOXICITY OF ARSENIC IN MAN AND ANIMALS

In animal experiments the oral LD_{50} has been found to vary from 15 to 293 mg/kg body weight in rats and from 10-150 mg/kg in other animals (Dieke and Richter, 1946; Harrison et al., 1958). The lower values refer to experiments with soluble arsenic compounds. Franke and Moxon (1936) found that the LD_{75} 48 hours after i.p. administration was 4-5 mg As/kg body weight for sodium arsenite and 14-18 mg/kg for sodium arsenate.

Acute effects seen in animals after oral exposure are similar to effects seen in human beings and include gastroenteritis, diarrhea and cardiovascular effects (Nelson et al., 1971; Selby et al., 1977).

REC 4991

A large number of acute arsenic poisonings are described in the literature, but few data exist on actual doses and type of compound. Vallee et al. (1960) estimated the lethal dose to be on the order of 70 to 180 mg for arsenic trioxide. Acute symptoms are due to severe gastrointestinal damage, resulting in vomiting and diarrhea and general vascular injury which may lead to shock, coma or even death. Other acute symptoms are muscular cramps, facial edema, and cardiovascular reactions (Holland, 1904; Done and Peart, 1971).

Acute symptoms have also been seen after airborne exposure to high concentrations of arsenic trioxide, causing severe irritation of nasal mucosa, larynx, and bronchi (Holmqvist, 1951; Pinto and McGill, 1953).

Reversible effects on the hematopoietic and cardiovascular systems and peripheral nervous disturbances with slow recovery have also been noted (Ohta, 1970; Heyman et al., 1956; Jenkins, 1966; Nagamatsu and Igata, 1975: O'Shaughnessy and Kraft, 1976; Hamamoto, 1955; Chhuttani et al., 1967; LeQuesne and McLeod, 1977).

Over the years, a number of large-scale poisonings have occurred due to contamination of beer (Kelynack et al., 1900), soy sauce (Mizuta et al., 1956), dried infant milk (Tokanehara et al., 1956), and well water (Yoshikawa et al., 1960). These episodes mainly caused subacute and chronic symptoms and will be discussed in the following sections.

5.2 CHRONIC TOXICITY OF ARSENIC IN MAN AND ANIMALS

5.2.1 Neurotoxic Effects

Arsenic neurotoxicity, including both peripheral and central nervous system injury, has long been recognized as being associated with acute, subacute, and chronic exposures to relatively high levels of inorganic arsenic. These have been well characterized as to their major pathophysiological features, clinical course, sequelae and associated histopathology.

Reynolds (1901) provided one of the earliest detailed descriptions of arsenic-induced neurotoxic effects in his report on the clinical assessment of more than 500 patients who had consumed arsenic-contaminated beer.

Neurological involvement started with sensory changes, e.g., paresthesias, hyperesthesias, and neuralgias, accompanied by considerable muscle tenderness. Varying degrees of motor weakness, progressing from distal to proximal muscle groups, also occurred and culminated at times in paralysis of affected muscle groups or extremities. Certain indications of central nervous system (CNS) damage, e.g., loss of memory and general mental confusion, were also observed but were discounted by Reynolds (1901) as being less likely due to arsenic than chronic alcoholism or concurrent excessive selenium intake.

Peripheral nervous system (PNS) effects similar to those described by Reynolds (1901) have since been observed in numerous other cases of acute, subacute, and chronic arsenic exposures (Silver and Wainman, 1952; Mizuta et al., 1956; Heyman et al., 1956; Jenkins, 1966; Hara et al., 1968; Chhuttani et al., 1967; Ishinishi et al., 1973; Nakamura et al., 1973; Nagamatsu and Igata, 1975; O'Shaughnessy and Kraft, 1976; Frank, 1976; Garb and Hine, 1977; LeQuesne and McLeod, 1977) and are now recognized as classic clinical symptoms of arsenic poisoning. Such symptoms include peripheral sensory effects characterized by the appearance of numbness, tingling, or "pins and needles" sensations in the hands and feet, as well as decreases in touch, pain, and temperature sensations in a symmetrical distribution. These symptoms are often variously accompanied by burning sensations, sharp or shooting pains, and marked muscle tenderness in the extremities. Peripheral neuritis symptoms originate distally and, over the course of a few weeks, often progressively become more widespread in both lower and upper extremities, usually appearing first in the feet and later in the hands.

Collectively, the above components of the classical clinical syndrome associated with excessive arsenic exposure are highly indicative of progressive peripheral polyneuropathy, involving both sensory and motor nerves, and most intensively affecting long-axon neurons. In addition, biopsy and autopsy studies have provided histopathological evidence verifying peripheral nerve damage, especially Wallerian degeneration of long-axon myelinated nerve fibers in cases of human arsenic exposure where frank neurological signs and symptoms were manifested (Heyman et al., 1956; Jenkins, 1966; Chhuttani et al., 1967; Ohta, 1970; LeQuesne and McLeod, 1977).

The pattern of development of peripheral neuropathic effects is closely associated with the type of exposure. Acute exposure to a single high dose of arsenic can produce a fairly rapid onset of both motor dysfunctions and paresthesias. In one report, the onset was within 10 days (LeQuesne and McLeod, 1977) after exposure. Slow, incomplete recovery is usually seen in these cases.

Under more chronic occupational exposure conditions to lower levels of arsenic compounds, the development of neuropathy symptoms can be more gradual and insidious, and not only bilateral, but unilateral polyneuropathies without motor paralysis have been reported (Ishinishi et al., 1973; Nakamura et al., 1973). Again, the time course for recovery from the neuropathies, once induced, tends to be slow and on the order of years. Gradual onsets of peripheral neuropathies and slow recoveries have also been reported with subacute or chronic exposures to arsenic via ingestion of contaminated soy sauce (Mizuta et al., 1956) or anti-asthmatic herbal preparations containing arsenic trioxide or arsenic sulfide (Tay and Seah, 1975).

It is difficult to determine the levels of arsenic associated with the induction of peripheral neuropathies. For subacute or chronic poisoning situations, information has been provided in only a few studies by which

effective exposure parameters can be estimated. Mizuta et al. (1956), for example, reported that peripheral neuropathies occurred in 20 percent of 220 patients of all age groups poisoned by ingestion of arsenic-contaminated soy sauce, with approximately 3 mg arsenic (likely as calcium arsenate) estimated to be ingested daily for 2-3 weeks, resulting in total effective doses up to approximately 60 mg. Also, Tay and Seah (1975) reported polyneuropathies in approximately 50 percent of 74 patients poisoned by daily ingestion of 3.3 or 10.3 mg/day of arsenic trioxide or arsenic sulfide in anti-asthmatic medicinal pills.

More subtle peripheral neurotoxic effects arising from chronic exposure to lower levels of arsenic in occupational or non-occupational groups are more difficult to establish, particularly as indexed by abnormal electromyographic or nerve conduction velocity findings. In one such study, Landau et al. (1977) reported relationships between length and intensity of occupational arsenic exposure (mainly to arsenic trioxide via inhalation) of smelter workers and alterations in peripheral nerve functioning. The manner in which the data were reported, however, precludes precise characterization of dose-effect/dose-response relationships.

In their study of arsenic in the drinking water of residents from Millard County, Utah, Southwick et al. (1981) conducted neurological examinations on all study participants 47 years of age and younger (see Section 7.1.2.2 for discussion of the total study population). Neurological examination revealed that conduction velocities for nerves studied (ulnar motor, median motor, ulnar sensory, median sensory, peroneal, sural) did not vary significantly with respect to age or community. In those individuals that exhibited below-normal conduction velocities, a slightly greater proportion was seen in exposed participants--12 percent of 67 controls versus 16 percent of 83 exposed. The

REC 4995

sural nerve seemed most often to be affected even after adjusting by a correction factor of 1.8 m/s/degree in individuals who had nerve temperatures below 30° C. (Velocities below 37 m/s at 30° C or above were considered abnormal). Slowing of sural nerve conduction was reported equally in exposed and control participants. Nerve conduction velocities regressed against annual arsenic dose and the log of the dose showed no significant associations.

Similar difficulties have been encountered in attempts to characterize dose-effect/dose-response relationships for arsenic-induced peripheral nerve functional deficits (as demonstrated by electromyographic recording techniques) in studies of two other populations chronically exposed to arsenic: (1) a population of Yellowknife Canadian Indians exposed via occupational contact with arsenic in a gold mining and smelting facility, or, in the case of the families of such workers, via arsenic emissions from the facility into the ambient environment (Canadian Public Health Assoc., 1978); and (2) a Nova Scotia population exposed, via geological arsenic contamination of wells, to levels >0.05 ppm arsenic in drinking water (Hindmarsh et al., 1977).

Several of the clinical reports discussed above not only document peripheral nerve damage but also contain descriptions of arsenic-induced central nervous system (CNS) disturbances or encephalopathy effects ranging in severity from memory losses and general mental confusion to convulsions, stupor, coma and even death (Heyman et al., 1956; Jenkins, 1966: Frank, 1976; Nagamatsu and Igata, 1975; O'Shaughnessy and Kraft, 1976; Garb and Hine, 1977). The onset and courses of such CNS effects have not been well defined, but they appear to closely parallel the development of peripheral neuropathy effects. Cases of prolonged encephalopathy indexed by electroencephalogram (EEG) recordings of abnormal brain wave patterns up to a year after cessation of exposure have been reported (Freeman and Couch, 1978; Bental et al., 1961). Such effects

REC 4996

appear to be a much less constant feature of arsenic-induced neurotoxic effects in adults than are peripheral neuropathies.

Certain studies suggest, in contrast, that children may be more susceptible to arsenic-induced CNS damage. For example, severe CNS deficits have been observed in children exposed for several months as babies to arsenic-contaminated powdered milk formulas in Morinaga, Japan (Hamamoto, 1955; Okamura et al., 1956; Yamashita et al., 1972; Masahiki and Hideyasu, 1973; Japanese Pediatric Society, 1973). Follow-up studies on the children exposed to arsenic as infants have revealed: (1) increased incidence of severe hearing loss (>30 dB) in 18 percent of 415 children examined compared to less than 1 percent incidence of hearing loss in corresponding age-group children; (2) increased incidence of abnormal electroencephalographic (EEG) brain wave patterns in 14 percent of the exposed children, more than double the expected rate for comparable normal pediatric populations; and (3) observations of increased incidences of persisting mental retardation, epilepsy, and other indications of severe brain damage.

In another study (Bencko and Syman, 1977), hearing losses in children were reported to be associated with arsenic exposure derived from emissions from a nearby coal-fired power plant combusting high-arsenic-content coal. Both air and bone conduction hearing losses were observed, suggesting inner ear damage. Failure to find analogous hearing losses in children exposed to atmospheric arsenic emitted from a copper smelter in the United States (Milham, 1977) has raised questions regarding arsenic-induced damage to the inner ear in children.

Very few animal toxicology studies have focused on investigation of neurotoxic effects of arsenic on the CNS. Rozenshtein (1970), for example, reported evidence of CNS functional deficits, as indexed by altered conditioned reflexes, as well as histopathologic evidence of CNS structural damage,

e.g,. pericellular edema and neuronal cytolysis in the brain, in rats exposed for three months to an arsenic trioxide aerosol resulting in an arsenic concentration of 46 μg/m^3. Similar but less severe effects were also obtained with exposure of other rats to a 3.7 μg As/m^3 aerosol. CNS deficits, indexed by impaired avoidance conditioning in the absence of demonstrable histopathologic changes in brain tissue, were also reported (Osato, 1977) for suckling rats administered 2 or 10 mg arsenic trioxide via stomach intubation over a 40-day period.

5.2.2 Cardiovascular Effects

A specific cardiovascular effect is "Blackfoot" disease, a peripheral vascular disease leading to gangrene of the toes, feet, legs and fingers. This disease has been reported in an area of Taiwan, where exposure to inorganic arsenic via drinking water is known to occur. In their skin cancer study of the Taiwanese population (see Section 7.1.2.2 for complete discussion of the total study population), Tseng and co-workers (1968, 1977) also investigated the occurrence of Blackfoot disease. The total prevalence of Blackfoot disease was lower than the prevalence of skin cancer, but higher in the younger age groups (Table 5-1). The overall prevalence rate for Blackfoot disease was 0.9-1.2 percent for males and 0.7 percent for females after age 39.

A group of 1108 patients with Blackfoot disease from the endemic area was identified during 1958 to 1975 (Tseng, 1977). There were 669 males and 439 females. Patients were included in the series if they had: 1) objective signs of ischemia, and 2) subjective symptoms of ischemia. Follow-up was attempted using a variety of methods to trace the subjects. At the end of follow-up, 528 patients had died, a fatality rate of 47.7 percent.

A history of typical ischemic symptoms such as numbness was used to estimate the date of onset of Blackfoot disease. Duration of intake of arsenic

REC 4998

TABLE 5-1. PREVALENCE OF BLACKFOOT DISEASE (per 1000) BY AGE AND ARSENIC EXPOSURE (ppm)

Arsenic content of drinking water (ppm)	Age 20-39	40-59	>60
<0.3	4.5	10.5	20.3
0.3 - 0.6	13.2	32.0	32.2
>0.6	14.2	46.9	61.4

Source: Adapted from Tseng, 1977.

water at the time of onset represents the period of time between first use of such intake and the time of onset of the disease. Duration of intake of arsenical water represents the duration of time during which the patient started drinking artesian well water up to the time of survey or up to the time of change of source of drinking water. For native patients, the duration is estimated to be equivalent to their ages, but for patients who came from areas without artesian wells the duration was counted as starting from the year of arrival.

A classification system of percentage of permanent disability was created and each patient was assigned to the appropriate category.

It was determined (determination not specified) that all patients with Blackfoot disease had consumed artesian well water before the onset of disease, and none of the residents of the endemic area who had consumed surface water or water from shallow wells developed Blackfoot disease.

In some parts of the arsenic endemic area, a new source of drinking water was provided in 1956. The incidence of Blackfoot disease was therefore examined in year of onset periods (1955 and before, 1956-1965, and 1966-1975). There were no cases of Blackfoot disease among area residents who were born after

REC 4999

the tap water supply was instituted in 1956. Furthermore, as the duration of intake of arsenical water increased (across all 3 exposure levels) the incidence of Blackfoot disease increased. In addition, the degree of permanent disability of patients was significantly correlated with duration of intake of arsenical water at time of onset of the disease.

There are also data indicating that other substances may be involved in the etiology of Blackfoot disease. Lu et al. (1977, 1978) found fluorescent compounds in water samples from an area with endemic Blackfoot disease. Of the compounds discovered, tentative identifications of D-lysergic acid and/or ergometrine, ergotamine and calciferol have been made (Irgolic, 1982). These substances may have been at least contributing factors to this disease, since some of them, or similar compounds, are known vasoactive agents.

Vascular changes were also noted among persons living in Antofagasta, Chile (see Section 7.1.2.2 for discussion of study groups). Raynauds syndrome and acrocyanosis were reported to occur in 30 and 27 percent, respectively, in a group of 100 persons studied by Borgono and Greiber (1972).

Raynauds syndrome has also been reported to occur among German vintners. Butzengeiger (1940) studied 180 persons and found that 22.8 percent had evidence of vascular disorders of the extremities. Butzengeiger (1949) studied 192 vinegrowers and found that 28.7 percent had ECG changes. There was, however, no control group.

In epidemiological studies of smelters (see Section 7.1.2.1 for complete discussion of studies), peripheral vascular disease has generally not been found. However, mortality studies indicate that there might be some cardiovascular effects, although study results have been conflicting. Thus, Axelson et al. (1978) found a higher mortality in cardiovascular disease, but analysis of the data indicate that if such an effect occurred it probably needed higher

exposure levels than those causing lung cancer. A study by Ott et al. (1974) indicated, on the other hand, that the arsenic-exposed workers had less mortality than expected.

In studies on workers at the Anaconda Copper Smelter in Montana, both Lee and Fraumeni (1969) and Lee-Feldstein (1983) reported that cardiovascular mortality was significantly elevated in the workers--SMR=118 and SMR=129, respectively ($p < 0.01$)--but not related to duration of arsenic exposure. In a study cohort of these same workers, Higgins et al. (1982) reported that cardiovascular mortality increased with increasing ceiling arsenic exposure among smokers, but not among nonsmokers--at 500-4999 ug/m^3, SMR=165 for smokers ($p < 0.01$), SMR=100 for nonsmokers; at >5000 ug/m^3, SMR=182 for smokers ($p < 0.01$), SMR=166 for nonsmokers. In contrast, Lubin et al. (1981) did not find an excess in cardiovascular disease mortality (SMR=108) in their study cohort of workers from the same smelter. The cohorts in all four of these studies were slightly different.

The conflicting findings of these reports suggest that the relationship between arsenic exposure and cardiovascular disease is quite complex and in need of additional research.

5.2.3 Teratogenesis and Developmental Effects

5.2.3.1 Animal Studies--In a recent review of the toxicological effects of prenatal exposure to arsenic, Hood (1983) discussed the number of variables that influence effects on offspring of maternal arsenic exposure during pregnancy. Included in the variables are the forms of arsenic administered, species and individual differences in susceptibility, dose level and exposure route, peak level attained in the conceptus, maternal metabolism and excretion, and timing of exposure during gestation; the length of the list being indicative of the complex nature of arsenic toxicity induced during prenatal exposure.

Teratogenic effects of arsenic compounds, at least at relatively high exposure levels, have been demonstrated in a number of animal species. Studies by Ridgeway and Karnofsky (1952), for example, demonstrated no gross abnormalities in chick embryos following injection of sodium arsenate into embryonate eggs at 0.20 mg As/egg on day 4 of gestation. Retardation in body weight gain and feather growth, as well as certain other abnormalities, were, however, observed in chickens hatched from arsenic-treated eggs.

Later experimental studies on mammalian species have demonstrated teratogenic effects of arsenic in hamsters, rats and mice.

Ferm and Carpenter (1968) produced malformations in 15-day hamster fetuses via intravenous (I.V.) injections of sodium arsenate into pregnant dams on day 8 of gestation at dose levels of 15, 17.5 or 20 mg/kg body weight. The variety of malformations obtained with prenatal arsenic exposure of hamsters--including exencephaly, encephaloceles, skeletal defects and genitourinary system defects and the effects of other related experimental manipulations, e.g., protective effects of co-treatment with selenium--were reviewed in a later report by Ferm (1977).

Willhite (1981) injected arsenate (20 mg/kg) or arsenite (2-10 mg/kg) into pregnant golden hamsters at day 8 of gestation and observed axial skeletal disorders in offspring--cranioschisis aperta with exencephaly and cranioschisis occulta--while 10 hours after dosing, embryos showed a delay in neural fold elevation and neural tube closure with arsenate exposure.

Teratogenic and embryotoxic effects of prenatal arsenic exposure of mice have also been reported (Hood and Bishop, 1972; Hood and Pike, 1972; Hood et al., 1977). Increased fetal resorption, decreased fetal weights and various malformations (such as exencephaly, micrognathia, agnathia, exophthalmos, anophthalmia, hydroencephaly, cleft lip, ectrodactyly, micromelia, fused vertebrae and forked ribs) were observed following single intraperitoneal (I.P.)

injections of sodium arsenate (45 mg As/kg body weight) in Swiss-Webster mice (the single injection occurring on one day between days 6 and 12 of gestation) (Hood and Bishop, 1972). Co-treatment with 2,3-dimercaptopropanol (BAL) reduced arsenic-associated malformations (Hood and Pike, 1972; Hood et al., 1977).

Many similar embryotoxic and fetal teratogenic effects, along with other effects (renal and gonadal agenesis), have also been observed following I.P. injections of sodium arsenate in pregnant rats (Beaudoin, 1974; Burk and Beaudoin, 1977), again at relatively high dose levels (e.g., 30 mg/kg body weight).

Compared to pentavalent arsenic, trivalent arsenic as the arsenite salt appears to be proportionally more embryotoxic. For example, the fetotoxic effects seen by Baxley et al. (1981) in mice exposed to 40-45 mg/kg As as arsenite were comparable to effects observed by Hood et al. (1978), in which a much higher level of arsenate (120 mg/kg As) was administered.

The above studies are suggestive of significant effects on reproduction and development of mammalian species being induced by prenatal arsenic exposure. However, only very minimal effects, or none at all on fetal development, have been observed in studies on chronic oral exposure of pregnant rat or mice dams to relatively low levels of arsenic via drinking water (Schroeder and Mitchener, 1971). Nadeyenko et al. (1978) reported that intubation of rats with arsenic solution at a dose level of 0.0025 mg/kg for a period of 7 months, including pregnancy, produced no significant embryotoxic effects and only very infrequent slight expansion of ventricles of the cerebrum, renal pelvises and urinary bladder. Also, Hood et al. (1977) reported that very high single oral doses of arsenate solutions (120 mg/kg) to pregnant mice were necessary to cause prenatal fetal toxicity, while multiple doses of 60 mg/kg on 3 days had little effect. This report suggests that the higher doses required with oral versus

parenteral exposure relate to the more rapid methylation to less toxic forms of oral arsenic owing to its initial passage through the liver, where methylation may occur. Similar results were obtained with mice in a later study (Hood et al., 1978).

Given the presence of biomethylation in mammalian species exposed to arsenic, the question arises as to whether fetotoxicity resides only in the untransformed inorganic arsenic or is due to some of the metabolites formed in vivo. Hood et al. (1982a) have demonstrated that methylated metabolites cross the placental barrier in mice given arsenite and that these methylated forms are actually the major form of arsenic in fetuses by 12 hours post-dosing.

Recently, three groups of investigators have reported their results on the comparative teratogenicity of methylated arsenicals, administered as such, to different species.

Willhite (1981) found no teratogenic response when pregnant golden hamsters were given methylated arsenic at single doses up to a level of 100 mg As/kg. Rogers et al. (1981) administered dimethylarsenic to pregnant CD rats and CD-1 mice on days 7-16 of gestation via oral gavage. Dosing was from 7.5 to 60 mg/kg/day for rats and 200 to 600 mg/kg/day for mice. Fetal and maternal toxicity was observed in both species. A teratogenic response in mice was confined to cleft palate in the 400- and 600-mg regimens. In the rat, there was a dose-dependent incidence of irregular palatine rugae.

Hood et al. (1982b) exposed pregnant golden hamsters to either dimethyl- or monomethyl arsenic at dosages of either 900 or 1000 mg/kg of the former agent and 500 mg/kg of the latter. The levels of dimethylarsenic administered were seen to be acutely toxic to dams and were associated with significant resorption rates and malformations in survivors. In the case of the monomethyl arsenic, the overall teratogenic potency was observed to be lower.

Harrison et al. (1980) exposed CD-1 mice to monomethyl arsenic by injection (1500 mg/kg salt, i.p.) on one of gestation days 8, 9, or 10. Treatment at days 9 and 10 of gestation resulted in increased resorption and mortality rates of 37 and 43 percent, respectively, while the day 8 group showed no such effects. Skeletal malformations were also seen at the 9 and 10 gestation day exposures. While details for dimethylarsenic were not provided, it was noted that such treatment also resulted in fetotoxicity and teratogenicity, with exencephaly the primary gross malformation observed.

The available data, in summary, indicate that while the methylated arsenicals are less teratogenic and fetotoxic on an equivalent dose basis, the nature of the effects is comparable. There also appears to be a species sensitivity difference for arsenical teratogenicity and fetotoxicity, the rat being more sensitive than mice or golden hamsters.

Animal studies on the effects of early postnatal administration of arsenic compounds on growth and development have generally failed to yield any significant positive results at sublethal arsenic dose levels. Tamura (1978), for example, reported no effects on the growth and development of postnatal rats fed arsenic trioxide in their diet from the 7th to 21st day following birth at a dose level of 1.5 mg/kg/day, in comparison to a 50 percent mortality rate at a 15.0 mg/kg body weight dose. Similarly, Ferslew and Edds (1979) observed no significant effects on growth or development of young swine fed arsanilic acid at 0.01 percent concentration for 31 days commencing at 3 weeks of age, despite observations of significant alterations by organo-arsenic of white blood cell counts, serum alkaline phosphatase activity, and other blood chemistry parameters and significant increases of arsenic in various soft tissues and urine. In another study (Heywood and Sortwell, 1979), both 3.75 and 7.5 mg/kg/day doses of an arsenic compound fed to adolescent or infant rhesus monkeys resulted in mortality in most of the exposed animals, but no notable

effects in growth or development of animals surviving the dosing period. Unfortunately, the lack of experimental data in the above studies on the effects of exposure across a range of dose levels, besides the ones employed, greatly limits their utility in terms of determining possible dose-effect or dose-response relationships between postnatal arsenic exposure and induced effects on growth and development.

It should be noted that, whereas some of the above animal studies provide highly suggestive evidence for arsenic effects on reproduction and development, at least at high exposure levels, one cannot confidently extrapolate the results to estimate the probability of occurrence of similar or analogous effects in man. Still, some suggestions of possible arsenic effects on human reproduction and development have been derived from certain epidemiology studies discussed below.

5.2.3.2 Human Studies--Available data are mainly from studies in Sweden on male and female smelter workers. These studies were not designed specifically to study effects of arsenic but rather to study the effects, in general, of the smelter work. While data from these studies suggest a low-level effect of smelter pollutants on neighboring (proximate) populations, the diverse agents involved preclude making conclusive statements about the specific effects of arsenic.

Congenital malformations were found to occur at about the same rate, 3.0 percent among women employed at the Rönnskär smelter, as among women living in six areas belonging to the hospital serving the Rönnskär area (Nordström et al., 1978c). However, mean birthweights were lower among offspring to female Rönnskär workers (Nordström et al., 1978a, 1978b).

The number of spontaneous abortions was also increased among women working in this smelter; the highest rate (17 percent) was found among women

employed during pregnancy or who had been employed prior to pregnancy and lived close to the smelter. Women working in close connection with smelting processes had a rate of 28 percent of spontaneous abortion compared with other female employees. When both parents were employed, the abortion rate was 19.4 percent compared to 13.5 percent when the father was not employed.

Studies on spontaneous abortion among women living in the vicinity of the smelter were also conducted (Nordström et al., 1978d). In four areas, the rate varied between 7.6 and 11.0 percent. The highest rate occurred in the area closest to the smelter, but many women employed at the smelter live in that area.

5.2.4 Hematological Effects

The hematopoietic system in man has been shown to be affected by arsenic exposure in cases of acute, subacute or chronic intake, taking the form of anemia, leukopenia, granulocytopenia and eosinophilia. Such effects appear to be reversible, the system recovering in a matter of weeks after exposure ends.

Hamamoto (1955), in his report of infant poisoning by arsenic-contaminated milk in Japan, described marked anemia and leukopenia with lymphocytosis in most of a group of 59 infant patients. Erythropoiesis was disturbed in bone marrow of 19 children studied. Within a month, the hematology appeared to show normal values. Similarly, Mizuta et al. (1956) found blood disturbances, including anemia with leukopenia and lymphocytosis, in subjects surveyed for ingestion of soy sauce contaminated with arsenic.

Two recent studies dealing with acute and subacute arsenic poisoning (Feussner et al., 1979; Lerman et al., 1980) have demonstrated arsenic-induced megaloblastic anemia. Feussner et al. (1979) demonstrated that arsenic was present in bone marrow by using electron-probe microanalysis.

Chronic exposure to arsenic occasions hematological effects which resemble those seen with subacute exposure. Terada (1960), in his survey of patients exposed to arsenic in well water contaminated by industrial activity in Niigata, Japan, saw anemia as a common feature, with the anemia being either normochromic (50 percent) or hyperchromic (30 percent). In their study on individuals living in communities in Utah where arsenic was present in drinking water, Southwick et al. (1981) also reported the presence of anemia in certain individuals; however, anemia was not significantly more prevalent in exposed populations. Anemia has been reported in subjects exposed to arsenic occupationally or in medicinals (Kyle and Pease, 1965; Westhoff et al., 1975).

In animals, decreased hemoglobin production has been seen in rats fed both arsenate (Mahaffey and Fowler, 1977) and arsenite (Byron et al., 1967) and in cats given either form orally (Massmann and Opitz, 1954). The study of Woods and Fowler (1977), in which arsenate was given orally to rats and mice at 20, 40 or 85 ppm in drinking water, showed that the sites of disturbance of the heme biosynthetic pathway by arsenate mainly involved depression of ALA-synthetase and heme-synthetase activity, with elevation in the urinary levels of chiefly uroporphyrin and also coproporphyrin. The increase in uroporphyrin appears to be specific to arsenic.

5.2.5 Hepatic Effects

In the reports of Hamamoto (1955) and Mizuta et al. (1956), dealing with arsenic contamination in infant milk and soy sauce, respectively, swollen livers appeared to be a common clinical feature. Of the children exposed to milk arsenic, all subjects presented with this feature (61/61). In the autopsies of fatal outcome cases, hemorrhagic necrosis and fatty degeneration of the liver were seen. In the survivors, liver function tests were not very revealing, being within normal limits in most cases. In both of the above episodes, liver size returned to normal after exposure ceased.

Over the years, chronic intake of arsenic has been reported to be associated with hepatic damage in the form of portal hypertension, malignant liver disease and cirrhosis. In the Manchester beer poisoning episode, Reynolds (1901) noted widespread liver disease in drinkers of such beer, with the extent of the disease being related to the amount of arsenic in the beverage.

The incidence of hepatic cirrhosis among German vintners has been reviewed by Luchtrath (1972), who noted that the frequency of liver cirrhosis decreased with the banning of arsenical pesticides. The use of arsenic as an anti-syphilitic is also known to be associated with hepatic cirrhosis (Baldridge, 1934).

Non-cirrhotic portal hypertension has been infrequently noted in the literature (Morris et al., 1974; Szuler et al., 1979). Szuler described one case report of presinusoidal portal hypertension in a patient taking an arsenic antiasthmatic for 55 years. Cirrhosis was absent and liver function was not disturbed.

In the smelter study by Axelson et al. (1978) there was a tendency towards an increased mortality in liver cirrhosis among arsenic-exposed workers.

5.2.6 Renal Effects

Functional and/or biochemical impairment of the human renal system is mainly seen in acute poisoning by arsine, AsH_3 (Uldall et al., 1970; Fowler, 1977). Oligouria and anuria progressing to renal failure are common acute responses. Persistent renal sequelae in subjects surviving the acute stage of arsine poisoning include chronic renal insufficiency and hypertension. Histologically, the injury is mainly tubular and interstitial.

Acute or chronic renal effects associated with arsenate or arsenite exposure are less well characterized. Gerhardt et al. (1978) have recently described a case of acute arsenic poisoning from contaminated illicit liquor.

Acute renal bilateral cortical necrosis was diagnosed in the patient who survived the acute stage to eventually develop reduced renal size and cortical calcification.

In the clinical survey of Hamamoto (1955) of Japanese infants poisoned with arsenic-contaminated milk, possible renal injury was diagnosed by the presence of hematuria, leukocyturia and glycosuria (23.7 percent, 42.3 percent and 13.5 percent, respectively). Reversibility of these indices was apparent, with only three percent of the patients still showing pathological changes after one month. Terada (1960) also noted proteinuria in cases of arsenic poisoning in Niigata, Japan, arising from ground water contamination from an arsenic plant.

5.2.7 Respiratory Effects Other Than Cancer

Nasal septum perforation is a rapid tissue response in workers encountering high airborne arsenic levels (NAS, 1977; Hine et al., 1977; Lundgren, 1954).

In the detailed smelter worker study of Lundgren (1954), 1,276 subjects in a worksite with levels up to 7 mg As/m^3 showed two types of respiratory disturbances relating to the nature of the processing and presumably the form of the arsenic. Refined arsenic handling was associated with septal perforation and rhinopharyngolaryngitis, while workers in the roaster, furnace, and connector areas showed tracheobronchitis and signs of pulmonary insufficiency. In the latter group, exposure was mixed, including both arsenic and sulfur dioxide. A recent report has suggested, furthermore, that workplace arsenic may also be present as the sulfide (Smith et al., 1976).

Chilean children exposed to arsenic in drinking water (Borgono et al., 1977) showed a chronic cough and bronchitic history.

5.2.8 Immunosuppressant Effects

The role of inorganic arsenic as an immunosuppressant in man is mainly inferred from indirect data accumulated over the years (Arsenic. NAS, 1977).

First, the therapeutic utility of arsenicals, such as arsenite-based Fowler's solution in the treatment of steroid-responding disorders and as a lymphocytostatic agent, suggests action as an immunosuppressant.

Secondly, certain manifestations indicative of likely immune system disorders have been observed with arsenic exposure, (e.g., the occurrence of herpes simplex and chronic pulmonary infections) and suggest a role of arsenic as an immunosuppressant (Arsenic. NAS, 1977). Histories of chronic cough and bronchitis in Chilean children exposed to arsenic in drinking water (Borgono et al., 1977) would tend to support such a role.

5.3 FACTORS AFFECTING ARSENIC TOXICITY

The most widely recognized and studied arsenic interactive behavior is with selenium, and much of the early data has been reviewed by Levander (1977).

The known antagonistic relationship of arsenic and selenium in a number of animal species was first described by Moxon and co-workers (Moxon and Dubois, 1939; Dubois et al., 1940), who also demonstrated the utility of dietary arsenic supplementation in protecting livestock from the toxic levels of selenium in certain fodders. Both penta- and trivalent arsenic are equally effective in protecting against selenium toxicity, and do so regardless of the chemical form by which selenium exposure occurs.

An understanding of the <u>in vivo</u> mechanisms by which arsenic imparts a protective effect on selenium toxicity has only recently been gained.

The ability of arsenic to retard the formation of volatile selenium in the form of dimethyl selenide (Kanstra and Bonhorst, 1953) apparently involves inhibition of microsomal methyl transferase, an enzyme sensitive to arsenite (Ganther and Hsieh, 1974). An overall protective effect still exists, however, since arsenic promotes the biliary excretion of selenium (Levander and Baumann, 1966; Ganther and Baumann, 1962). According to Levander (1977), enhanced biliary

clearance of selenium in the presence of arsenic probably involves an excretory conjugate of both, since selenium likewise enhances the biliary excretion of arsenic.

Rössner et al. (1977) showed a protective effect for arsenite against the cytotoxicity of selenite, using suspension cultures of mouse fibroblasts exposed to these agents at 10^{-5} to 10^{-11} M. Interestingly, selenite, in turn, had only a low protective effect against arsenite cytotoxicity.

Few data exist for interactive relationships between arsenic and other elements. In one of the few pertinent studies bearing on this issue, the effects of concomitant oral exposure to cadmium, lead and arsenic versus single-agent exposure effects have been reported by Mahaffey and Fowler (1977). Cadmium and arsenic together retarded weight gain in young adult rats to a greater extent than either element alone.

6. ARSENIC MUTAGENICITY

Various inorganic compounds of arsenic have been tested for mutagenicity in a variety of test systems ranging in complexity from bacteria to peripheral lymphocytes of exposed human beings. Information on these tests has been reviewed herein and elsewhere (Flessel, 1978; NAS, 1977; Leonard and Lauwerys, 1980; WHO, 1981). The following chapter is divided into five major sections discussing studies indicative of mutagenic damage, as well as interactions of arsenic with other mutagens and possible mechanisms of mutagenic action.

6.1 GENE MUTATION STUDIES

6.1.1 Prokaryotic Test Systems (Bacteria)

Arsenic does not appear to induce gene mutations in bacteria (Table 6-1). Sodium arsenite ($NaAsO_2$) was tested for its ability to induce reverse mutations in E. coli (Nishioka, 1975). Three bacterial strains auxotrophic for tryptophan were tested for growth in the absence of tryptophan after arsenic treatment. Nishioka reported that arsenic induced mutations in wild type cells and in cells deficient in excision repair ($uvrA^-$) but not in cells deficient in recombinational repair ($recA^-$). This suggested that the rec function is necessary for arsenic-induced mutagenesis in E. coli.

The observations by Nishioka were not reproducible in subsequent studies by Rossman et al. (1980). In these latter studies, the authors examined sodium arsenite-induced mutagenesis in five strains of E. coli, all auxotrophic for tryptophan and carrying different mutations for DNA repair capacities. In addition, Rossman et al. used three protocols for quantifying the presence of mutant cells: the spot test, the plate test and the fluctuation test. Arsenite did not increase the mutation frequency in any E. coli strain using any of the

TABLE 6-1. SUMMARY OF MUTAGENICITY OF ARSENIC: GENE MUTATIONS

Nishioka, 1975	Reverse mutation in E. coli Strains: WP2 (trp^-) WP2 uvrA ($uvrA^-$, trp^-) CM571 ($recA^-$, trp^-)	$NaAsO_2$ 8.0×10^{-4} M in WP2 1.6×10^{-4} M in WP2 uvrA 1.6×10^{-4} M in CM571 Source: Nakarai Chemical LTD (reagent grade) Solvent: H_2O	$NaAsO_2$ positive for mutations in WP2 and WP2 uvrA but not in CM571. Increases were approximately 10x background.	1. Doses of arsenite were selected to kill 60-70% of cells. 2. Lack of mutagenesis in CM571 suggests that a rec function is required for mutagenesis in E. coli. 3. Rossman et al. (1981) were unable to reproduce these mutation studies. They claimed (a) that the induced mutation frequencies observed by Nishioka were within the normal range of background, (b) that they observed a 31-fold difference in cytotoxicity studies compared to Nishioka, and (c) that Nishioka used an incorrect method for determining mutation frequency.

TABLE 6-1. (continued)

Weak positive for mutation.	1. Study lacking sufficient experimental details.
Amacher and Paillet, 1980	Forward gene mutation at the thymidine kinase (TK) locus in mouse L5178Y cells.	Na_2HAsO_4 Doses tested: (0.83×10^{-4}, 1.1×10^{-4}, 1.47×10^{-4}, 1.96×10^{-4}, 2.26×10^{-4} M) Source: Fisher Solvent: Normal saline	Negative	1. Exposed 3 hrs at 37°C. 2. Survival ranged from 66% at the low dose to 35% at the high dose. 3. Other metals such as cadmium, nickel, and trans-platinum were positive.
Rossman et al., 1980	Induction of forward mutations in Chinese hamster cells in vitro at HGPRT locus and the sodium-potassium ATPase locus.	$NaAsO_2$ (0.5×10^{-6} M, 2 days) ouabain resistance (5.0×10^{-6} M, 1 hour) ouabain resistance (20×10^{-6} M, 1.5 hours) thioguanine resistance (100×10^{-6} M, 25 min) thioguanine resistance	No increased mutation	1. UVC and MNNG used as positive controls. 2. Doses of arsenite used varied from slightly inhibitory to cell growth to fairly toxic.

TABLE 6-1. (continued)

Reference	Test system	Chemical Information	Results	Comments
Oberly et al., 1982	Forward gene mutation at the thymidine kinase (TK) locus in mouse L5178Y cells.	$NaAsO_2$ (3.8×10^{-6}, 7.7×10^{-6}, 11.5×10^{-6}, 15.4×10^{-6}, 19.2×10^{-6} M) Na_2HAsO_4 (7.5×10^{-5}, 9.7×10^{-5}, 11.8×10^{-5}, 14.0×10^{-5} M) Source: Mallinckrodt	$NaAsO_2$ was negative in the presence of Aroclor-induced rat S-9 mix; $NaAsO_2$ was positive for the three highest doses tested in the absence of S-9 mix; Na_2HAsO_4 was negative in the absence of an Aroclor-induced rat S-9 mix; Na_2HAsO_4 was positive at the three highest doses tested in the presence of an S-9 mix.	1. Chemical exposure was for 4 hours. 2. Only positive data were shown; negative results were only mentioned in the text. 3. The spontaneous mutation rate varied a great deal between experiments; between 2.5 and 17.9 mutants per 10^5 survivors. Most of the arsenic-induced mutant frequencies were between or just slightly above this spontaneous range. 4. The increases in mutant frequencies occurred at very low survival levels for both compounds; the highest doses caused 97% lethality. 5. At survivals above 10% none of the mutant frequencies exceeded the limits of the control mutant frequency range.

test protocols. Indeed, arsenic showed a dose-dependent suppression of mutations in strain $WP44_S$-NF. This strain carries a mutation (tif-1) which confers a thermally inducible SOS repair system (error-prone repair) resulting in normal spontaneous mutation at 30°C and a 20-fold increase in mutation at 42°C. The presence of sodium arsenite in the medium was sufficient to suppress this temperature-induced increase in the mutation frequency by one-half. This observation suggests that arsenic may inhibit SOS repair, a pathway which is highly important in bacterial mutagenesis. Such a repair pathway has not been detected in mammalian cells.

Rossman et al. (1980) offered explanations for the discrepancies between their results and those of Nishioka. First, they pointed out that the arsenic-induced mutation frequencies reported by Nishioka were all within the normal range of background. Second, they observed a 31-fold difference in cytotoxicity in the same bacterial strains. Third, they noted that Nishioka used an incorrect method for determining mutation frequency, basing his calculations on the initial size of the cell inoculum instead of on the final size of the plated population.

Arsenite and arsenate have also been found to be negative in the Ames Salmonella microsome assay (Lofroth and Ames, 1978). Although this work is reported only in abstract form, it may be assumed the assay was performed properly as Ames is a cited author.

Consideration of the above results alone, however, should not be taken as proof that inorganic arsenic is non-mutagenic. Bacterial systems are generally insensitive for the detection of metal mutagens because of the large amount of magnesium salts, citrate and phosphate in the minimal medium which prevent the entry of metal mutagens into bacterial cells (McCann et al., 1975).

6.1.2 Eukaryotic Microorganisms (Yeast, Fungi)

Sodium arsenite was tested for its activity in inducing reverse mutation and mitotic gene conversion in the yeast Saccharomyces cerevisiae (Singh, 1983). The diploid strain used in this study (D7) is auxotrophic for tryptophan, isoleucine, and valine, and measures gene conversion at the trp locus and reverse mutation at the ilv locus. Arsenite was inactive for gene conversion and weakly positive for mutation. This study was generally lacking in details and raw data were not shown.

6.1.3 Mammalian Cells In Vitro

Sodium arsenate was tested for the induction of forward mutations at the thymidine kinase locus in mouse L5178Y cells (Amacher and Paillet, 1980). Doses of arsenate were selected such that between 66 percent to 35 percent of cells survived a three-hour treatment. Arsenate was found not to increase the spontaneous mutation rate in these cells, while other known or suspected mutagenic metals (cadmium, nickel, and trans-platinum) were positive.

Using the same system, Oberly et al. (1982) tested sodium arsenate and sodium arsenite in the presence and in the absence of an Aroclor-induced rat S-9 mix. Sodium arsenite gave positive results at the three highest doses when tested in the absence of S-9 mix. In the presence of S-9 mix, the results were reported to be negative, although no data were presented. Sodium arsenate gave positive results at the three highest doses tested in the presence of S-9 mix. Again, without presenting data, the outcome in the absence of metabolic activation was reported to be negative. The authors concluded that these two arsenic compounds were weak mutagens. There are, however, several problems with this interpretation. First, the spontaneous mutation rate varied a great deal in these studies: between 2.5 and 17.9 mutants per 10^5 survivors. Most of the arsenic-induced mutant frequencies fell between or just slightly above

this spontaneous range. Second, the increases in mutant frequencies occurred at very low survival levels for both compounds; the highest doses used caused 97 percent lethality. Thus, at survivals exceeding 10 percent none of the mutant frequencies exceeded the limits of the range of control mutant frequencies. Taking these observations into consideration, the authors' conclusions do not seem well supported.

Sodium arsenite was also tested for the induction of forward mutations at two loci in V79 cells (Chinese hamster lung fibroblasts) (Rossman et al., 1980). The two genes studied were hypoxanthine guanine phosphoribosyl transferase (HGPRT) and membrane-bound sodium potassium ATPase. Mutations in these two enzymes were enumerated through the observation of cell clones resistant to thioguanine or ouabain, respectively. Both the concentration of the chemical as well as the incubation times were varied; there was, however, no increase in the mutation frequency at either locus. The positive controls, UVC (ultraviolet light 254 mm) and methylnitronitrosoguanidine (MNNG) were effective in elevating the mutant frequency.

6.2 CHROMOSOMAL ABERRATION STUDIES

6.2.1 Chromosomal Aberrations In Vitro

A large number of studies indicate that both trivalent and pentavalent arsenic compounds are capable of breaking chromosomes in vitro (Table 6-2). One of the earliest reports on the clastogenic potential of arsenic was from a study performed with mitogenically stimulated human peripheral lymphocytes (Petres and Hundeiker, 1968). Although the test compound was reported to be Na_2HAsO_3, it is assumed the authors meant Na_2HAsO_4. Positive results were reported, although no actual raw data were presented.

Paton and Allison (1972) tested both sodium arsenite and sodium arsenate for the induction of chromosomal aberrations in human diploid fibroblasts and

Reference	Test System	Chemical Information	Results	Comments
Wan et al., 1982	Induction of chromosome aberrations in vitro in CHO cells and human peripheral lymphocytes (HPL).	$NaAsO_2$ (10^{-6}, 5×10^{-6}, 10^{-5} M) CHO; (0.5×10^{-6}, 10^{-6}, 5×10^{-6} M) HPL Na_2HAsO_4 (5×10^{-5}, 8×10^{-5}, 10^{-4} M) CHO. Purity: Analytical grade Source: Fisher Scientific Co. Solvent: H_2O	Dose-related increase for both compounds in CHO. $NaAsO_2$ gave dose-related increase in HPL.	1. Trivalent was 5 to 10 x more potent than pentavalent. 2. All doses tested were inhibitory to CHO cell growth. 3. Arsenic present for entire culture period (22 hrs.) in CHO cells, and final 48 hrs of culture in HPL.
Poma et al., 1981b	Induction of chromosomal aberrations in mouse bone marrow and spermatogonia in vivo.	As_2O_3, single I.P. injection (4, 8 and 12 mg As/kg). Solvent: H_2O	Negative in bone marrow. Negative in spermatogonia.	1. Mouse strain: Swiss Albino 2. Sex: male. 3. Age: 12 weeks 4. Number of animals per dose group: 4-8. 5. Cells per animal: 100. 6. Sacrifice times: 12, 24, 36, 48 hrs post injection.

mitogenically stimulated human peripheral lymphocytes. Sodium arsenite gave positive results in both cell types while sodium arsenate was tested only in lymphocytes and was reported to be negative. Since arsenate (which most investigators find to be considerably less potent than arsenite) was tested at a lower concentration, the negative result is not surprising.

In a more recent study, the effects of sodium arsenite and sodium arsenate on chromosomal aberration frequencies were examined in cultured human peripheral lymphocytes and in Syrian hamster embryo cells (Larramendy et al., 1981). Both compounds gave highly significant increases in chromosomal aberrations in both cell types. Arsenite was more potent by approximately an order of magnitude, and both compounds induced mainly chromatid-type aberrations.

Nakamuro and Sayato (1981) tested six arsenic compounds for the induction of chromosomal aberrations in cultured human peripheral lymphocytes and in human skin fibroblasts. All arsenic compounds tested were clastogenic and all gave linear dose-response functions in lymphocytes. Trivalent compounds were more potent than pentavalent compounds. The observed order for decreasing potency was As_2O_3 > $AsCl_3$; $NaAsO_2$ >> Na_2HAsO_4 > H_3AsO_4; As_2O_5 (Figure 6-1). $NaAsO_2$ and H_3AsO_4 were positive, showing linear dose-response functions in fibroblasts. All compounds induced predominantly chromatid-type aberrations.

In another study, the effects of sodium arsenite and sodium arsenate on the induction of chromosomal aberrations in human peripheral lymphocytes exposed <u>in vitro</u> were examined using two protocols (Nordenson et al., 1981). In the first protocol, cells were mitogenically stimulated with PHA, arsenic was added after 24 hours and cells were harvested after 72 hours (48-hour arsenic exposure). Using this method, sodium arsenite was found to increase the frequency of chromatid breaks and gaps in a dose-dependent fashion. Sodium arsenate was reported to be negative, but these investigators employed

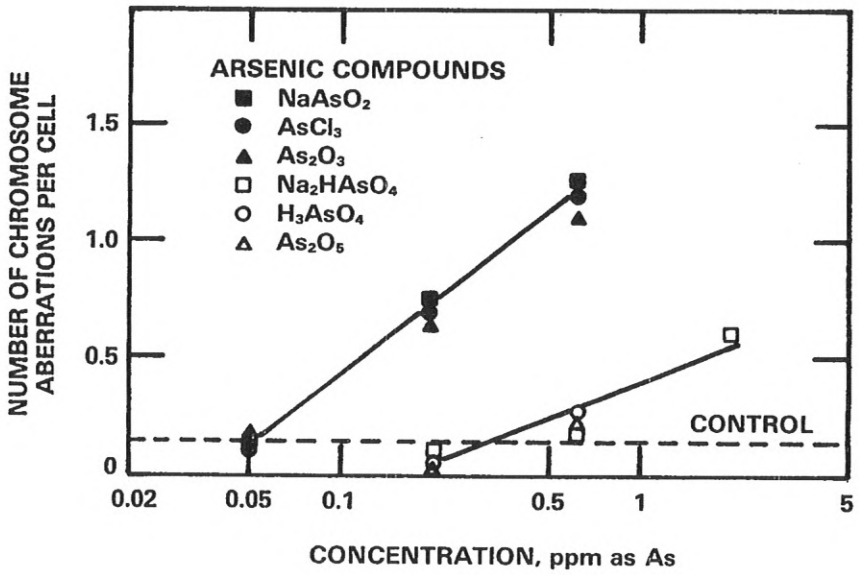

Figure 6-1. The induction of chromosome aberrations in cultured human peripheral lymphocytes by six arsenic compounds.

Source: Nakamuro and Sayato (1981).

the same concentrations of arsenate as were tested for arsenite. It is possible that higher doses of arsenate would also have yielded positive results. In the second protocol, G_0 (unstimulated) lymphocytes were exposed to arsenic for 24 hours, and the cells were washed, stimulated with PHA and harvested after 48 additional hours. Using this protocol the authors reported that "$NaAsO_4$" was negative. One may assume that the authors meant $NaAsO_2$, since having observed a lack of activity for arsenate in the first protocol, it would seem unwarranted to test it in the second. If the test compound was indeed arsenite, these observations suggest that arsenic has its effect through some influence on DNA synthesis and not by directly damaging DNA.

In the most recent study on *in vitro* clastogenic effects of arsenic compounds, sodium arsenite and sodium arsenate were tested in CHO cells and human peripheral lymphocytes (Wan et al., 1982). Both compounds showed dose-dependent increases in aberrations in CHO cells; arsenite was also positive in lymphocytes. Again, trivalent arsenic was 5 to 10 times more potent than pentavalent arsenic.

6.2.2 Chromosomal Aberrations In Vivo

There is only one report in the literature (excluding abstracts) in which the clastogenic effects of arsenic were tested in a mammalian species *in vivo* (Poma et al., 1981b). These authors examined chromosomal aberration frequencies in mouse bone marrow cells and spermatogonia after administration of As_2O_3 (4, 8 and 12 mg of arsenic/kg). This trivalent form of arsenic was previously shown to be the most potent form *in vitro* (Nakamuro and Sayato, 1981). Four to 8 animals were included in each dose group; animals were killed at 12, 24, 36 and 48 hours after exposure and 100 metaphase cells per animal were scored. This represents an acceptable protocol, and the study appears to have been properly performed. There was no significant increase in aberrations in either

bone marrow or spermatogonia following arsenic treatment. An important question in this study is whether sufficiently high doses were tested. The LD_{50} for arsenic trioxide in rats is 104 mg As/kg; thus, the highest dose used in this mouse study is only 13 percent of the rat LD_{50}. One can crudely compare the doses of arsenic trioxide which were effective in vitro to those used in this study by simply equating the test animal to an equivalent volume of water. Such a comparison indicates the mice were "1.6×10^{-4} M" effective for arsenic while the same compound was effective for inducing aberrations in vitro at approximately 0.7 to 7.0×10^{-4} M arsenic. Clearly this represents a very crude comparison since intact animals can bind, compartmentalize and excrete a toxicant while cells in culture cannot. Thus, it is not clear whether higher doses should have been tested in this study.

6.2.3 Chromosomal Aberrations and SCE in Cells of Arsenic-Exposed Human Beings

The majority of studies indicate that people exposed to arsenic due to occupation or pharmaceutical treatment display increased levels of chromosomal aberrations and SCE in peripheral lymphocytes (Table 6-3). It should be noted that most of the studies which have examined aberrations and SCE are poor in quality due either to errors in experimental protocol, misclassification of aberrations, poor choice in controls and/or not performing studies in a blind fashion.

Beckman et al. (1977) examined the frequency of chromosomal aberrations in peripheral lymphocytes of nine smelter workers who were exposed to arsenic. The levels and the forms of arsenic to which the workers were exposed were not indicated. A statistically significant increase in aberrations was found in the exposed population. There are several problems with this study. First, the authors use an incorrect definition of gaps. They state: "Gaps are commonly defined as achromatic regions exceeding the width of a chromosome." This, in

TABLE 6-3. SUMMARY OF MUTAGENICITY OF ARSENIC: CHROMOSOMAL ABERRATIONS AND SCE IN CELLS OF EXPOSED HUMANS

Reference	Test System	Chemical Information	Results	Comments
Beckman et al., 1977	Chromosomal aberrations in lymphocytes of 9 smelter workers exposed to arsenic.	Arsenic from smelter	Positive, six-fold increase in percent aberrant cells; eight-fold increase in aberrations per cell.	1. Authors used an incorrect definition of gaps. 2. Cells cultured too long (72 hours). 3. Cells scored per individual were unknown. 4. Number of control individuals and cells per control individual were not specified. 5. Some workers were also exposed to lead and selenium.
Nordenson et al., 1978	Chromosomal aberrations in lymphocytes of 33 smelter workers.	Arsenic from smelter	Positive	1. Divided workers into high exposure (18 individuals), medium exposure (11), low exposure (4) and new employees (6). 2. The controls were an unspecified number of apparently historical controls. 3. No dose effect. 4. Wrong definition of gaps. 5. Cell culture time too long. 6. Large difference between controls and new employees.

TABLE 6-3. (continued)

Reference	Test System	Chemical Information	Results	Comments
Burgdorf et al., 1977	Compared SCE and chromosomal aberrations in lymphocytes of 6 patients treated with arsenic, with results from 44 control individuals.	All treated with Fowler's solution (1% $KAsO_2$ in H_2O), for time periods between 4 and 27 years. Five of these individuals had not been treated for at least 24 years.	No difference in frequencies of chromosomal aberrations. SCE frequencies were increased more than 2-fold in arsenic-treated patients.	1. Cultured cells for 72 hours - too long for examination of aberrations. 2. No indication that study was scored blind. 3. Patients exposed to other agents (e.g. 4000 rad x-irradiation, 5000 rad x-irradiation, fluoroscopy twice weekly while receiving arsenic, 4 had asthma).
Petres et al., 1977	Chromosome aberrations in lymphocytes of 31 individuals exposed to arsenic.	Arsenic exposure related to treatment for psoriasis or associated with vine-growing.	Positive, nine-fold increase in aberrations among arsenic-exposed individuals.	1. 31 exposed individuals, 31 controls. 2. Cell culture time too long (72 hours). 3. Scored both gaps and achromatic lesions - same aberration. 4. Scored secondary constrictions - not generally considered an aberration. 5. No indication of the number of cells per person scored. 6. Saw a 5-fold increase in aneuploidy among arsenic-exposed individuals, always hypodiploidy, which suggests an artifact.

TABLE 6-3. (continued)

Reference	Test System	Chemical Information	Results	Comments
Nordenson et al., 1979	Chromosome aberrations and SCE in peripheral lymphocytes of 8 psoriatic patients treated with arsenic.	Total arsenic dose per individual varied from a low of 300 mg up to 1200 mg. Most had not been treated for 15 years.	Psoriatic patients treated with arsenic showed significantly higher (three-fold) levels of aberrations compared to control psoriatics. Psoriatic patients treated with arsenic had the same levels of SCE as controls.	1. Slides were scored blind. 2. Investigators controlled for age and sex but not for ethanol use, smoking, drug use, or infection. 3. The increases in aberrations were not dose-related. 4. Cultured cells for 72 hours: too long for aberrations. 5. Scored too few cells for SCE in control patients; provided total number of cells scored, but number of cells per individual was unknown.

TABLE 6-3. (continued)

Reference	Test System	Chemical Information	Results	Comments
Wen et al., 1981	SCE in peripheral lymphocytes of 13 Blackfoot disease patients (arsenic-exposed) and 13 controls.	Exposure to arsenic from well water; years of use ranged from 15 to 58. Most had not consumed contaminated water for 12 years.	Arsenic-exposed individuals showed small but statistically higher SCE level. Ranges for arsenic-exposed (9.1 to 17.5 SCE/cell) and controls (7.8 to 12.0 SCE/cell) showed considerable overlap.	1. Patients exposed to a large number of other drugs, including pantopan, scopolamine, promethazine hydrochloride, meperidine, ketamine hydrochloride, Pyrabital, Valium, ampicillin, Kanamycin, Sedes, diphenhydramine hydrochloride, Kolantyl, Complamin, Venostatin, Ulcerin, metoclopramide, Sulpyrin, chloramphenicol, reserpine, Bartropine, dextromethorphan, furosemide, and Hustazol. 2. All patients had undergone leg or foot amputation.

fact, is a definition for a break. A gap is commonly defined as an achromatic lesion not exceeding the width of a chromatid arm. Second, the total number of cells examined are given but the cells per individual worker, cells per individual control, and total number of control individuals are not listed. Third, these investigators cultured the lymphocytes for 72 hours, a duration 24 hours longer than optimum, since most chromosome aberrations are cytotoxic, and cells with such lesions generally do not survive more than a single cell cycle. After 72 hours of culture, the majority of cells have divided three times, eliminating many damaged cells. Clearly, however, this type of error tends to underestimate the frequency of aberrations. Finally, workers were also exposed to other potentially clastogenic agents such as lead and selenium.

A report one year later by the same group (Nordenson et al., 1978) extended this study to a total of 33 smelter workers. In this study individuals were grouped into high exposure (18 people), medium exposure (11), low exposure (4) and new employees (6). The groupings were based on the nature of the job; quantitative measurements of exposure were not performed. The workers were reported to have a higher level of chromosome aberrations than did the controls. However, the controls were of an unspecified number and, apparently, historical, the definition of gaps was incorrect, cells were cultured for 72 hours, and large differences were found between historical controls and new employees. Due to these problems, the positive findings reported are questionable.

Burgdorf et al. (1977) compared SCE and chromosomal aberration frequencies in lymphocytes of six patients treated with arsenic (for asthma, psoriasis or anxiety) to results from 44 control individuals. All patients had been treated with Fowler's solution (1% $KAsO_2$ in water) for time periods varying between 4 and 27 years. Five of these individuals had not been treated for at least 24 years. The authors found no difference in frequencies of chromosomal aberrations, but reported a more than 2-fold higher SCE frequency in arsenic-treated

patients. Each of the patients had an SCE level which was significantly higher than the mean level for controls. Problems with this study included a 72-hour culture period for aberrations, no indication that slides were scored "blind," and the fact that patients were exposed to other agents (4000 rad x-irradiation, 5000 rad x-irradiation, fluoroscopy twice weekly concomitant to arsenic exposure).

In a similar study, Petres et al. (1977) compared chromosome aberrations in lymphocytes of 31 arsenic-exposed people to 31 controls. Arsenic exposure resulted from treatment for psoriasis or was associated with vine-growing. The levels and forms of arsenic exposure were not indicated. A statistically significant increase in aberrations was found in the exposed group. These authors also reported a five-fold increase in aneuploidy among arsenic-exposed individuals. Problems in this study include: (1) a 72-hour cell culture period; (2) no indication of the number of cells per person scored; (3) scoring both gaps and achromatic lesions, identical endpoints; (4) scoring secondary constrictions, which are generally not considered to be aberrations; and (5) all aneuploid cells were hypodiploid, which suggests an artifact.

Nordenson et al. (1979) compared chromosome aberrations and SCE in peripheral lymphocytes of 8 arsenic-treated psoriatic patients to 8 untreated psoriatic controls. Total arsenic dose per individual varied from a low of 300 mg up to 1200 mg. Most had not been treated for 15 years. Psoriatic patients treated with arsenic showed significantly higher levels of aberrations compared to controls, but showed similar frequencies of SCE. The increase in aberrations was not related to the total arsenic dose. Although these authors controlled for age and sex, there was no apparent control for smoking, drug use or ethanol consumption. An average of 15 cells per individual were scored for SCE; generally, 20 cells per individual is considered the acceptable minimum. As in the other studies, the cells were cultured for 72 hours.

Frequencies of SCE were compared in 13 patients exposed to arsenic in drinking water to SCE frequencies in 13 control individuals (Wen et al., 1981). All patients displayed symptoms of Blackfoot disease, a peripheral vascular disease resulting from chronic arsenic intoxication. Patients had used contaminated water for 15 to 58 years; most had switched to uncontaminated tap water 12 years before this study. Arsenic-exposed individuals showed a small but statistically higher SCE level. Ranges for arsenic-exposed (9.1 to 17.5 SCE/cell) and controls (7.8 to 12.0 SCE/cell) showed considerable overlap. Sources of error in this study are large since the arsenic-exposed group had also been exposed to over 20 different pharmaceuticals.

6.3 OTHER STUDIES INDICATIVE OF MUTAGENIC DAMAGE

6.3.1 Preferential Killing of Repair-Deficient Bacterial Strains

Arsenic compounds have generally been found to preferentially kill bacteria that carry particular mutations in DNA repair pathways (Table 6-4). Both sodium arsenite and sodium arsenate gave positive results in the B. subtilus "rec assay" (Nishioka, 1975). In this assay, test chemicals are spotted onto filter discs and the discs are placed at the centers of a bacterial lawn composed of rec^+ cells (H17) or rec^- cells (M45, deficient in recombinational DNA repair). The size of the zone of growth inhibition is measured for both strains, with a differential response (more killing of M45) indicative of a DNA-damaging agent. Sodium arsenite was reported to give a moderately positive response while sodium arsenate was reported to give a weakly positive response.

The results for sodium arsenate were reproduced in the B. subtilus rec assay and positive responses for four other arsenic compounds (As_2O_5, As_2O_3, $AsCl_3$, $3AsO_5$) have been reported (Kanematsu et al., 1980). These authors indicated that all arsenic compounds gave "strongly positive" responses (greater than 6 mm growth difference).

Tkeshelashvili et al., 1980	Fidelity of DNA synthesis components: 1. E. coli DNA polymerase. 2. Artificial DNA template poly-[d(A-T)]. 3. Radiolabeled nucleotide triphosphates	Na_2HAsO_4 (0.1, 0.5, 1.0., 5.0 mM) As_2O_5 (0.1, 0.5, 2.5, 10.0 mM) Source: Either ICN Corp. or J.T. Baker Purity: 99.9%	Neither arsenic compound affected the "natural" error rate.	1. Other metals such as chromium increase the error rate in this system. 2. This is a very artificial system, i.e., the polymerase is a bacterial-repair enzyme, the DNA is an artificial template containing only two nucleotide bases and the system is carried out entirely in vitro.
Fornace and Little, 1979	Induction of DNA-protein crosslinking and single-strand DNA breaks in mouse C3H/10T 1/2 cells (alkaline elution).	$NaAsO_2$ (1 mM) Solvent: Cell culture medium	No crosslinks detected. Positive for single-strand breaks (equivalent to 120 rad of X-ray)	1. Cells were treated for 1 hour; only 2.2% of cells survived this treatment.

Sodium arsenate and sodium arsenite were also found positive in the E. coli microsuspension test (McCarroll et al., 1981). In this assay, a variety of E. coli strains carrying mutations for DNA repair are incubated in multiwell microplates with a serially-diluted test compound. The highest dose at which growth is evident is compared in wild type and DNA repair-deficient strains. Again, a differential sensitivity to growth inhibition is indicative of DNA damage. Sodium arsenate was found to preferentially inhibit the growth of strain WP100 ($recA^-$, $uvrA^-$) compared to wild type cells. This strain is deficient in excision as well as recombinational repair. Sodium arsenite was positive in strains WP100 and CM611 ($lexA^-$, $uvrA^-$). This latter strain is deficient in excision repair and is not inducible for post-replicational error-prone (SOS) repair. Negative results were seen in strains which are only deficient in excision repair, implying that arsenic-induced damage is not repaired by this pathway or that arsenic has no effect on enzymes which repair spontaneous damage through excision repair.

6.3.2 DNA Damage in Mammalian Cells In Vitro

Fornace and Little (1979) examined the effects of sodium arsenite on the induction of DNA-protein crosslinks and single-strand DNA breaks in mouse C3H/10T 1/2 cells using alkaline elution (Table 6-4). This technique measures the rate at which radiolabeled DNA passes through a polyvinyl chloride filter having a defined pore size. Treatment of cells for one hour did not induce DNA-protein crosslinks but did cause a significant increase in single-strand breaks. The level of breakage observed was equivalent to treating the cells with 120 rad of x-ray. It should be noted that the treatment protocol was highly toxic with only 2.2 percent of cells surviving the treatment.

6.3.3 Fidelity of DNA Synthesis

Some metals, such as chromium, are thought to be mutagenic by interfering with a DNA polymerase-editing function. As a result they increase the rate at

which "errors" are made in DNA replication. Loeb and co-workers have designed an *in vitro* system that measures the rate at which particular nucleotides are inappropriately incorporated into DNA (Sirover and Loeb, 1976; Tkeshelashvili et al., 1980) (Table 6-4). In this system, the DNA template is a repeating sequence of adenine and thymidine (poly[d(A - T]) which is incubated with *E. coli* DNA polymerase I, and ^{32}P-labelled dTTP and ^{3}H-dGTP. By monitoring the ratio of the two isotopes in acid precipitable material one can quantify the frequency with which an error in incorporation is made. Neither sodium arsenate nor arsenic pentoxide (As_2O_5) affected the "natural" error rate. Chromium was shown to be positive in this assay. It should be cautioned that this is a very artificial system, i.e., the polymerase is a bacterial-repair enzyme, the DNA is an artificial template containing only two nucleotide bases, and the system is carried out entirely *in vitro*.

6.3.4. Induction of Sister Chromatid Exchanges (SCE) In Vitro

Arsenic compounds have been extensively tested for the induction of SCE in a variety of cell types *in vitro*. Almost without exception the results are positive (Table 6-4). Significant increases in SCE frequencies were shown in human peripheral lymphocytes treated with sodium arsenite (Nordenson et al, 1981; Larramendy et al., 1981; Anderson, 1983; Crossen, 1983) and sodium arsenate (Larramendy et al., 1981; Crossen, 1983). The studies by Crossen, however, suggested that individuals may vary significantly in their susceptibility to arsenic-induced SCE. Crossen noted that arsenite increased the SCE frequency in cells from two donors but had no effect in cells from two other donors. Arsenate increased the SCE frequency in one donor, had no effect in two other donors and slightly decreased the SCE frequency in a fourth donor. Crossen also used a protocol in which cells were exposed to arsenic in G_o (unstimulated), washed and then cultured for SCE analysis. The results were

similar to those seen for chromosomal aberrations (Nordenson et al., 1981), i.e., neither arsenite nor arsenate increased SCE levels when treatment occurred during a nonreplicative phase. Again, these results indicate that arsenic must be present during DNA synthesis (SCE occur during S phase) to have an effect.

Arsenic has also been tested for SCE induction in Chinese hamster lines *in vitro*. Wan et al. (1982) reported a dose-related increase in SCE in CHO cells exposed to sodium arsenite, while Ohno et al. (1982) reported significant increases in the SCE frequency in DON cells exposed to single doses of sodium arsenite, sodium arsenate, and arsenic pentoxide.

6.4 INTERACTIONS OF ARSENIC WITH OTHER MUTAGENS

6.4.1. Bacterial Studies

The effects of sodium arsenite (1 mM) on the frequencies of UVC-induced mutations were measured in *E. coli* strain WWP_2 (trp^-, $uvrA^-$), a strain deficient in excision repair (Rossman et al., 1977). Arsenite was found to reduce the number of UVC-induced mutations by 30 to 40 percent. This observation suggests that arsenic may interfere with SOS (error prone) DNA repair, and may, therefore, be a bacterial antimutagen (Table 6-5).

In a later study, Rossman (1981) further examined the effect of sodium arsenate and sodium arsenite on frequencies of UVC-induced mutations. In *E. coli* WP2, which is proficient in all repair pathways, arsenite increased UVC mutagenesis at doses up to 0.25 mM and then decreased the mutation frequency at higher doses. The increase in mutation was seen only in excision repair-proficient strains. These observations suggest that arsenic interferes with excision repair at low doses and interferes with SOS repair at higher doses.

Fong et al. (1980) examined the effect of sodium arsenate on the frequency of UVC-induced single-strand DNA breaks in *E. coli* (Table 6-5). The presence

TABLE 6-5. SUMMARY OF MUTAGENICITY OF ARSENIC: INTERACTIONS WITH MUTAGENS

Reference	Test System	Chemical Information	Results	Comments
Rossman et al., 1977	Interaction of UVC and arsenic in E. coli for mutation. Strain WWP_2 (trp^-, $uvrA^-$).	$NaAsO_2$ (1 mM) plus 1.25, 5.0, and 10 J/m^2 UVC	$NaAsO_2$ reduced the number of UVC-induced mutants by 30 to 40 %.	1. Suggests that arsenic interferes with SOS repair. 2. May not be relevant to mammals since this type of repair has not been found.
Rossman, 1981	Interaction of arsenic and UVC in the induction of mutations of E. coli. Strains: WP2 (trp^-) $WP2_s$ (trp^-, $uvrA^-$) WP6 (trp^-, $polA1^-$) WP5 (trp^-, $lexA^-$) WP10 (trp^-, $recA^-$)	$NaAsO_2$ (0.1, 0.25, 0.5, 0.75 mM) plus 5.6 J/m^2 in WP2. Na_2HAsO_4 (0.1, 0.3, 0.5 mM) plus 5.6 J/m^2 in WP2. $NaAsO_2$ (0.2 mM) plus 5.6 J/m^2 in WP2, 0.6 J/m^2 in $WP2_s$, 1.2 J/m^2 in WP6, 0.6 J/m^2 in WP5, 0.6 J/m^2 in WP10 Source: Fisher Chemical Co.	Arsenite increased UVC mutagenesis in WP2 at doses up to 0.25 mM and then decreased mutation frequency at higher doses. This increase was not seen with arsenate. The effect with arsenite was seen only in excision repair-proficient strains.	1. Observations indicate that arsenic may interfere with excision repair at lower doses and with SOS repair at higher doses.

TABLE 6-5. (continued)

Reference	Test System	Chemical Information	Results	Comments
Fong et al., 1980	Induction of single-strand (S.S) DNA breaks in E. coli after exposure to UVC light (alkaline sucrose sedimentation). Strains used: WP2-wild type WP6-(polA), lacks DNA polymerase used in repair WP2-(uvrA), deficient in excision repair.	$NaAsO_2$ (1,2,3,4, 5 mM)	1 mM arsenic inhibited the induction of S.S. breaks in WP2 and WP6 after exposure to UVC (40 J/m^2 and 10 J/m^2, respectively). 3 mM arsenic prevented the rejoining of S.S. breaks after UVC (5 J/m^2) in WP2 (uvrA) cells.	1. Arsenic prevents enzymatic incision in DNA after exposure to ultraviolet light. 2. Authors speculate this may result from arsenic-induced depletion of cellular ATP. 3. Arsenic may inhibit post-replicational repair since it prevented rejoining of S.S. breaks in cells deficient in excision repair.
Jung et al., 1969	Inhibition of unscheduled DNA synthesis (UDS) in human epidermal cells seen in biopsies derived from seven normal volunteers after UV irradiation.	Na_2HAsO_4 (10^{-5}, 10^{-6} M)	Arsenic inhibited UVC-induced UDS.	1. Tissue biopsies were incubated with arsenic for either 1 hr or 4 hrs prior to UVC exposure. 2. There were no dose- or incubation time-related effects on inhibition of UVC-induced UDS. 3. Actual numbers were not shown.

Poma et al., 1981a (abstract)	Interaction between arsenic and ethyl methanesulfonate in the induction of chromosome aberrations in vivo in Swiss-albino mice: bone marrow, and spermatogonia.	Arsenic (12 mg As/kg) EMS (200 mg/kg) pre- or post-treatment.	No interaction	1. No experimental details, work described in an abstract.
Sram, 1976	Chromosomal aberrations in bone marrow cells of ICR mice. Each dose group consisted of 5 female mice. Animals sacrificed 24 hours after a single dose of TEPA, scored 250 metaphases/group (assume 50/animal).	$NaAsO_2$ in drinking water for 8 weeks. 10 mg/l (7.7×10^{-5} M) 100 mg/l (7.7×10^{-4} M) TEPA 2 mg/kg	$NaAsO_2$ alone did not appear to induce aberrations although the spontaneous rate was not clearly indicated. The lower dose of arsenic in drinking water did not affect the frequency of TEPA-induced aberrations. The higher dose of arsenic resulted in a synergistic increase in the aberration rate.	1. This study was lacking in experimental details.

TABLE 6-5. (continued)

Reference	Test System	Chemical Information	Results	Comments
Sram, 1976	Interaction of $NaAsO_2$ and TEPA for dominant lethals in ICR mice; each treated and control group consisted of 20 males and 40 females/week. Mating continued for 3 to 8 weeks after the application of TEPA.	$NaAsO_2$ in drinking water for 8 weeks/ generation, males were exposed for 4 generations prior to mating. 10 mg/l (7.7×10^{-5} M) 100 mg/l (7.7×10^{-4} M) TEPA 2 mg/kg	$NaAsO_2$ alone did not appear to induce dominant lethals, although it is not clear what the spontaneous rate was. There appeared to be a positive interaction between TEPA and the higher exposure to arsenic.	1. This study was badly lacking in experimental details. 2. It was not indicated at what time after TEPA administration the increase in dominant lethals was seen, thus it is not known which germ cell stage was affected.

of strand breaks in DNA was measured by alkaline sucrose sedimentation. One mM arsenite was found to inhibit the induction of strand breaks in WP2 (wild type) and WP6 polA (lacks DNA polymerase I) after exposure to UVC. The presence of 3 mM arsenate in growth medium prevented the rejoining of strand breaks after UVC exposure in WP2 uvrA cells (excision repair-deficient). The authors interpreted these observations to suggest: (1) that arsenic prevents enzymatic incision of DNA after UVC exposure (UVC alone does not cause strand breaks), and (2) that arsenic may inhibit post-replicational repair since it prevented rejoining of breaks in cells deficient in excision repair. The authors further speculated that the inhibition of enzymatic incision may result from arsenic-induced cellular depletion of ATP.

6.4.2 Mammalian Cells In Vitro

The interaction of sodium arsenate and UVC on levels of unscheduled DNA synthesis (UDS) was measured in cells from human skin biopsies taken from seven volunteers (Jung et al., 1969; Table 6-5). Arsenate was tested at two concentrations (10^{-5}, 10^{-6}M) and for two preincubation periods (1 and 4 hrs). Arsenic was reported to inhibit the level of UVC-induced UDS, although there were no dose- or time-related effects. The actual numbers were not reported in the paper.

Rossman (1983) examined the effect of arsenite on UVC-induced HGPRT mutations in V79 cells. Although no data were provided in this report, the outcome was reported to be negative.

6.4.3 Mammalian Cells In Vivo

The interaction of arsenic and ethylmethanesulfonate (EMS) on levels of chromosome aberrations *in vivo* was examined in bone marrow and spermatogonial cells of Swiss-albino mice (Poma et al., 1981a). The arsenic dose was 12 mg As/kg combined with either pre- or post-treatment with 200 mg/kg of EMS. No

interactions were reported. It should be cautioned that this information has only been reported in abstract form.

Sram (1976) examined the effects of including sodium arsenite in drinking water (7.7×10^{-5}, 7.7×10^{-4} M) on frequencies of tris (1-aziridinyl) phosphine oxide (TEPA)-induced (2 mg/kg) chromosomal aberrations in ICR mouse bone marrow cells. Animals were given arsenic-laced water for 8 weeks, were injected with TEPA, and killed after 24 hours. A total of 250 cells per dose group (5 animals per dose) were scored. Sodium arsenite alone did not appear to induce aberrations, although the spontaneous rate was not clearly indicated. The lower dose of arsenic in drinking water did not affect the frequency of TEPA-induced aberrations. The higher concentration of arsenic resulted in a synergistic increase in the aberration rate. This study was, unfortunately, lacking in experimental details.

Sram (1976) did essentially the same study for the examination of dominant lethality in ICR mice. Animals were maintained for 4 generations prior to mating on arsenic-laced drinking water (7.7×10^{-5}, 7.7×10^{-4} M). TEPA was again given as a single dose of 2 mg/kg. Each treated animal and a control group of 20 males was mated with 40 females per week. The matings continued for 3 to 8 weeks after mutagen application. Sodium arsenite alone did not appear to induce dominant lethals, although the spontaneous rate was not clearly indicated. The lower dose of arsenic in drinking water did not affect the frequency of TEPA-induced dominant lethals. The higher concentration of arsenic resulted in a synergistic increase in the dominant lethal rate. It was not indicated at what time after TEPA administration the increase in dominant lethals occurred; thus, it is not known which germ cell stage was affected. This study also failed to provide experimental details.

6.5 POSSIBLE MECHANISMS OF ACTION

Arsenic is unusual in several respects. First, unlike the overwhelming majority of clastogenic agents, arsenic does not appear to directly damage DNA. Rather, it seems to have its effect through some interference with DNA synthesis. This contention is supported by the observations that arsenic induces chromosomal aberrations and SCE only when it is present during DNA replication. Incubation and removal of arsenic before DNA synthesis has no effect (Nordenson et al., 1981; Crossen, 1983).

Second, arsenic is highly unusual in that it induces chromosomal aberrations and SCE while it fails to induce gene mutations. In this regard, it is like diethylstibesterol, which is another highly unusual carcinogen. X-irradiation, although capable of producing chromosome aberrations as well as gene mutations, is much more potent for the former endpoint. There is a small possibility, however, that the discrepancy for arsenic may be founded on an artifact. Protocols for gene mutation assays generally involve cellular incubation with the test agent for relatively short time periods (2 to 3 hours), while protocols for aberrations often involve the presence of the test agent for one or two entire cell cycles (12 to 48 hours). Thus, in the latter protocol, arsenic would be present for at least an entire S phase for all cells, whereas, when tested for gene mutations, arsenic would be present for only a small fraction of the S phase in approximately one-third to one-half of the cells. Since the evidence available suggests that arsenic has its effect only during DNA replication, this may account for the discrepancy.

Arsenic has long been known to be a sulfhydryl reagent capable of inhibiting a number of thiol-dependent enzyme systems, trivalent forms being much more potent than pentavalent forms (Leonard and Lauwerys, 1980). Thus, one possible mechanism of action for arsenic would be the inhibition of DNA repair enzymes. The work of Rossman (1981) in bacteria and Jung (1969) in human

skin cells *in vitro* lends support to this hypothesis. Also, the observations of Sram (1976) on the interactions of arsenic with TEPA for the induction of chromosomal aberrations and dominant lethals support such a contention. The potencies of trivalent and pentavalent arsenicals as sulfhydryl reagents are similar to their potencies as clastogens and SCE-inducing agents. Observations which counter this hypothesis are the reports by Rossman that arsenic has no effect on the frequency of UVC-induced mutations in mammalian cells *in vitro* and the fact that arsenic does not affect the frequency of EMS-induced aberrations *in vivo* (Poma et al., 1981a).

Another possible mechanism for the action of arsenic may be through its occasional incorporation into the DNA backbone in place of phosphorus. There are several lines of evidence to support this mechanism. First, for this to occur, arsenic would have to be present during DNA synthesis and would have no effect on non-dividing cells. Second, such a mechanism could explain why arsenic is clastogenic (such a bond would be weaker than the normal phosphodiester bond) but does not induce gene mutation. Third, arsenic has been shown to cause strand breaks in DNA (Fornace and Little, 1979). X-irradiation, a potent clastogen and poor inducer of gene mutations, also predominantly causes strand breaks as its major DNA lesion. An argument against such a mechanism is the observation that the trivalent forms are more potent than pentavalent forms, while pentavalent arsenic should be more likely to substitute for phosphorus in DNA. Therefore at present, there is no single, unambiguous explanation for the mechanisms by which arsenic breaks chromosomes or induces SCE.

7. ARSENIC CARCINOGENICITY

The case for the association of inorganic arsenic with skin and lung cancer as well as other visceral carcinomas has been extensively reviewed (Arsenic NAS, 1977; IARC, 1973 and 1980; NIOSH, 1975; Hernberg, 1977; Sunderman, 1976, Pelfrene, 1976; Kraybill, 1978; Wildenberg, 1978; Pershagen and Vahter, 1979; WHO, 1981). The following chapter is divided into three major sections discussing human studies, animal studies and quantitative carcinogenic risk estimates.

7.1 HUMAN STUDIES

The literature on arsenic carcinogenicity in humans is summarized in Table 7-1. This subsection on human studies will first focus on clinical pathophysiological aspects of arsenic carcinogenesis, followed by pertinent epidemiological studies of arsenic-induced carcinogenesis.

7.1.1 Clinical Aspects of Human Arsenic Carcinogenesis

In man, chronic exposure to arsenic induces a characteristic sequence of changes in skin epithelium, proceeding from hyperpigmentation to hyperkeratosis which may be histologically described as showing keratin proliferation of a verrucose nature with derangement of the squamous portions of the epithelium or may even be described in some cases as squamous cell carcinomas.

Late onset skin cancers, associated with arsenic exposure, appear to be of two histopathological types: squamous carcinomas in the keratotic areas and basal cell carcinomas. In one study dealing with skin cancer after prolonged use of Fowler's solution (Neubauer, 1947), the ratio of types was approximately 1:1.

Arsenic-associated skin cancers differ from those of ultraviolet light etiology by occurring on areas generally not exposed to sunlight, e.g. palms and soles, and occurring as multiple lesions (Arsenic. NAS, 1977; Pershagen

REC 5053

TABLE 7-1. SUMMARY OF CASE REPORTS AND EPIDEMIOLOGIC STUDIES OF CANCER OR PRECANCEROUS LESIONS IN PERSONS EXPOSED TO ARSENIC

Media	Study Population	Author(s)	Type of Study	Results	Highlights and Deficiencies
Air	Smelter workers-Tacoma, Washington (Analysis of deaths for 1946-1960)	Pinto and Bennett (1963)	Proportionate mortality	No difference in lung cancer proportionate mortality between exposed and unexposed workers.	Workers leaving the plant before retirement were not included. In the classification of workers by exposure, the "non-exposed" group apparently were exposed since they also had high levels of arsenic in the urine.
	Smelter workers-Tacoma, Washington (follow-up from 1950-1971)	Milham and Strong (1974)	Cohort	40 observed lung cancer deaths versus 18 expected ($P < 0.001$).	Urinary arsenic levels of persons living around the smelter decreased with distance from the smelter.
	Smelter workers-Tacoma, Washington (follow-up from 1949-1973)	Pinto et al. (1977)	Cohort	32 observed respiratory cancer deaths, versus 10.5 expected ($P < 0.05$). Dose response seen by urinary arsenic levels and by duration and intensity of exposure.	Study consisted of only pensioners.
	Smelter workers-Tacoma, Washington (Follow-up from 1941-1976)	Enterline and Marsh (1982)	Cohort	104 respiratory cancer deaths observed versus 52.5 expected ($P < 0.01$). Dose response found by intensity and duration of exposure.	Short-term high-intensity arsenic exposures appeared to have a greater effect than did long-term low-intensity exposures; SO_2 exposure was found to have little or no effect.
	Smelter workers-Anaconda, Montana (Follow-up from 1938 to 1963)	Lee and Fraumeni (1969)	Cohort	147 respiratory cancer deaths observed versus 44.7 expected ($P < 0.01$). Dose response found by intensity and duration of exposure.	A dose response was found between exposure to sulfur dioxide and respiratory cancer mortality. Exposure to sulfur dioxide could not be separated from exposure to arsenic, however.
	Smelter workers-Anaconda, Montana (Follow-up from 1964 to 1977)	Lubin et al. (1981)	Cohort	146 respiratory cancer deaths versus 88.7 expected ($P < 0.01$).	Exposure to sulfur dioxide was not found to have an independent effect on cancer risk.
	Sample of 1800 of the smelter workers-Anaconda, Montana (Follow-up from 1938-1977)	Welch et al. (1982); Higgins et al. (1982)	Cohort	24 respiratory cancer deaths versus 4.6 expected ($P < 0.01$) in the heavy exposure category. Dose response found by intensity (both time-weighted average and ceiling level categories) of exposure.	Analysis of lung cancer mortality by SO_2 exposure found that SO_2 did not play an important role in the respiratory cancer process.

TR 1740

TABLE 7-1. (continued)

Media	Study Population	Author(s)	Type of Study	Results	Highlights and Deficiencies
Air	Smelter workers-Anaconda, Montana (Follow-up from 1938 to 1977)	Lee-Feldstein (1983)	Cohort	302 respiratory cancer deaths observed versus 105.8 expected ($P < 0.01$). Dose response found by duration and exposure.	
	Lung cancer from the parish where the Ronnskar smelter is located	Axelson et al. (1978)	Case-control	For smelter workers, the lung cancer mortality odds ratio was 4.6; there also was a significantly ($P < 0.02$) elevated risk of leukemia and myeloma among smelter workers.	Exposure to sulfur dioxide did not appear to be associated with lung cancer.
	Lung cancer deaths in the city of Saganoseki-machi, Japan	Kuratsune et al. (1974)	Case-control	58% of lung cancer cases were found to be former smelter workers versus 15.8% in controls.	The cause of death listed on the death certificate was validated using detailed pathologic analysis.
	Copper smelters in Sagnoseki-machi, Japan	Tokudome and Kuratsune (1976)	Cohort	29 trachea, lung, and bronchus cancer deaths versus 2.44 expected ($P < 0.01$); 3 observed colon cancer deaths versus 0.59 expected ($P < 0.05$). A lung cancer dose response was seen by length of employment and level of exposure.	The latent period ranged from 13 to 50 years, with an average of 37.6 years.
	Smelter workers in Magna, Utah	Rencher et al. (1977)	Proportionate mortality and cohort	7 percent of the deaths were lung cancer deaths compared to 0 to 2.2 percent for other factory workers and 2.7 percent for the State; the lung cancer death rate was found to be 10.1 per 10,000 versus 2.1 and 3.3 per 10,000 for mine workers and the State, respectively.	
	Residents living near a smelter in El Paso. Texas	Rom et al. (1982)	Case-control	No association was found between lung cancer and distance from the plant.	Effects of migration, smoking and occupation were not considered.

REC 5055

TABLE 7-1. (continued)

Media	Study Population	Author(s)	Type of Study	Results	Highlights and Deficiencies
Air	Residents of Deer Lodge and Silver Bow Counties, Montana	Newman et al. (1976)	Ecological correlation	There was an increase found in the incidence of lung cancer among men. In one of the cities there was also an increase in lung cancer among women.	No adjustment was made for cancer cases which may be occupational.
	All counties in the United States with smelters	Blot and Fraumeni (1975)	Ecological correlation	Average lung cancer mortality rates were significantly elevated for both males and females in 36 counties with smelters processing copper, lead, or zinc ores.	
	Residents near a smelter in Utah	Lyon et al. (1977)	Case-control	No association between cancer and distance from the smelter was found.	Lymphoma cases which may have an association with arsenic exposure were used as controls. Effects of smoking, migration, and occupation were not considered.
	Residents near Ronnskarverken smelter in northern Sweden	Pershagen et al. (1977)	Ecological correlation	A significantly higher mortality rate for lung cancer was noted for men in the exposed area. The increase was no longer significant when occupational cases were excluded, however.	When excluding occupational cases of lung cancer from the study population, lung cancer cases for a comparable occupational group were not excluded from the comparison population.
	Population surrounding an arsenical pesticide facility	Matanoski et al. (1976, 1981)	Ecological correlation	The lung cancer mortality for males in the census tract in which the plant was located was 3-4 times higher than the control tracts ($P < 0.05$).	The difference in the lung cancer mortality rate in the index tract could not be explained by occupation.
	Arsenical sheep dip manufacturing workers	Hill and Faning (1948)	Proportionate mortality	29.3 percent of deaths were due to lung cancer versus 12.9 percent of deaths among workers in the same geographic area who were not exposed to arsenic ($P < 0.05$). The excess in cancer deaths was mainly due to an excess in lung cancer and skin cancer.	

TABLE 7-1. (continued)

Media	Study Population	Author(s)	Type of Study	Results	Highlights and Deficiencies
Air	Arsenical pesticide manufacturing workers	Ott et al. (1974)	Proportionate mortality and cohort	16.2% and 3.5% of deaths in the exposed group were from cancer of the respiratory system and from lymphatic and hematopoietic cancers, except leukemia, respectively, versus 5.7 and 1.4% in the controls; the cohort mortality study found 20 respiratory cancer deaths and 5 deaths of the lymphatic and hematopoietic tissues versus 5.8 and 1.3 expected, respectively (both significant at $P < 0.01$).	A respiratory cancer mortality dose response was not found below an average dosage of 3890 mg of arsenic, but above that dosage there was a good dose response. It should be noted, however, that all of the respiratory cancer at or below 3890 mg had less than one year of exposure. Thus, it is unlikely that those deaths were due to arsenic exposure.
	Retirees of an arsenical pesticide plant in Baltimore, Maryland (follow-up from 1960 to 1972)	Baetjer et al. (1975)	Proportionate mortality and cohort	The proportionate mortality ratio (PMR) was 6.58 for respiratory cancer ($P < 0.05$); for cause-specific mortality the observed-to-expected ratios were 16.67 for respiratory cancer and 50 for lymphatic cancer (both with $P < 0.05$).	The cohort study was limited to pensioners only.
	Retirees of an arsenical pesticide plant in Baltimore Maryland (follow-up 1946 to 1977)	Mabuchi et al. (1979)	Cohort	12 observed lung cancer deaths versus 3.6 expected ($P < 0.05$); a dose response by duration of employment was seen for those with exposure of high intensity.	
	Wenatchee Valley orchard workers in the state of Washington	Nelson et al. (1973)	Cohort	No difference was found between the cohort and the state of Washington for overall cancer mortality or for lung cancer mortality.	
	German vintners	Roth (1958)	Proportionate mortality	Of 47 autopsies among vintners with chronic arsenic intoxication, 64% of the deaths were due to cancer, 60% to lung cancer; 6 of the 47 and 13 of the 47 were reported to have liver and skin tumors, respectively.	No controls were used. There was no indication of how the autopsy cases were selected.

TABLE 7-1. (continued)

Media	Study Population	Author(s)	Type of Study	Results	Highlights and Deficiencies
Water	Residents of a section of Taiwan with high levels of arsenic in the drinking water	Tseng et al. (1968); Tseng (1977)	Cross-sectional	A skin cancer prevalence rate of 10.6/1000 for those drinking well water was found compared to 0/1000 for a control area. The skin cancer rate followed a dose response by arsenic concentration in the water.	
	Sample of inhabitants of Antofagasta, Chile	Borgono and Greiber (1972)	Cross-sectional	Abnormal skin pigmentation and hyperkeratosis were found in Antofagasta where high arsenic levels in the water were reported. No skin cancers were reported, however.	
	Residents of certain departments in the province of Cordoba, Argentina, exposed to high levels of arsenic in the water	Bergoglio (1964)	Proportionate mortality	The proportion of cancer deaths was higher than for the province as a whole (23.84% versus 15.3%, $P < 0.05$). Of the cancer deaths, respiratory cancer was reported to be 35% and skin cancer 2.3%.	The data were apparently not age-adjusted. No comparison was made of the percentage of respiratory and skin cancer deaths in the affected departments with the respective proportion for Cordoba Province.
	Patients at a dermatology clinic in eastern Argentina	Arguello et al. (1938)	Case reports	The largest proportion of cases in the clinic (82%) came from areas with the highest incidence of chronic endemic regional arsenical intoxication.	The study was not population-based.
	Residents in an area of Lane County, Oregon	Morton et al. (1976)	Cross-sectional	The prevalence of skin cancer was not found to be associated with arsenic concentrations in the water.	The sample size was relatively small.
	Residents of Hinckley and Deseret, Utah, where relatively high arsenic contamination of the drinking water supplies existed and Delta, Utah, which had very little arsenic contamination of the water supply	Southwick et al. (1981)	Cross-sectional; mortality comparison	There was no dermatological evidence of arsenic ingestion in Hinckley or Deseret. No evidence of unusual cancer mortality patterns in Hinckley was found.	Sample size was very small-only 145 in the exposed group, 105 in the controls. The town of Hinckley is rather small for a mortality analysis. The population was only 400 in 1970.

TABLE 7-1. (continued)

Media	Study Population	Author(s)	Type of Study	Results	Highlights and Deficiencies
Water	353 cases of Blackfoot disease and 353 controls matched for sex and age in an area of Taiwan with an endemic arsenic contamination of the water supply	Ch'i and Blackwell (1968)	Case-control	Significantly ($P < 0.01$) more cases than controls were found to consume deep well water (known to be contaminated with arsenic) and population had a low socioeconomic status.	
	Two persons living in an area of Taiwan with endemic high levels of arsenic in the water supply	Astrup (1968)	Case report	Both individuals had developed Blackfoot disease.	
Water, soil, dust	One female child	Falk et al. (1981b)	Case report	Child, with a history of pica, developed hepatic angiosarcoma with associated congenital dysplasia of the liver and an infantile benign hemangioendothelioma suggesting pre-natal as well as post-natal etiological factors.	
Milk	A group of children in Japan	Yamashita et al. (1972)	Cohort	Hyperpigmentation and depigmentation were found to be prevalent in about 15 percent of the survivors approximately 15 years after exposure.	There was no comparison group.
Arsenical medicinals	Patients being treated with arsenical medicinals	Hutchinson (1888)	Case reports	Six patients treated with arsenical medicinals exhibited the keratotic lesions associated with arsenical poisoning.	
Arsenical medicinals	Patients being treated for skin diseases and various internal disorders with arsenical medicinals.	Neubauer (1947)	Case reports	143 individuals with epitheliomas and who had taken arsenical medicinals.	

TABLE 7-1. (continued)

Media	Study Population	Author(s)	Type of Study	Results	Highlights and Deficiencies
Arsenical medicinal	Patients treated with Fowler's solution (an arsenical medicinal) by a private practitioner	Fierz (1965)	Cohort	106 of the 262 patients reporting for physical examination reported hyperkeratosis; 21 cases of skin cancer were also found. The response increased with increasing dose.	Less than 45% of the cohort presented themselves for physical examination, and the author himself reported that the patients reporting for examination were not a representative sample. Furthermore, no controls were used.
Arsenical medicinal	Patients treated with arsenical medicinals	Reymann et al. (1978)	Cohort	Of 389 persons treated with arsenical medicinals, 41 internal malignant neoplasms were found to occur versus 44.6 expected. No increase in internal malignant neoplasms was found by dose.	There was no control group. Internal organs presumably include the lung, and there was no control for smoking, a major confounder with regard to lung cancer.
Arsenical medicinal (Fowler's Solution)	Patients treated with Fowler's solution	Cuzick et al. (1982)	Cohort	A statistically significant association of ingestion of Fowler's solution with deaths from internal malignancies was not found. A subset of 142 of the 487 in the cohort was examined and 49% were found to show dermal signs of arsenicism including skin cancer (11%).	In the subset of 142, deaths from internal malignancies occurred only in those who had previously demonstrated dermal signs of arsenicism, leading the authors to conclude that perhaps persons who show signs of arsenicism are at a greater risk of death from internal malignancies.
Arsenical medicinal (Fowler's Solution)	Male patient	Regelson et al. (1968)	Case report	Hemangioendothelial sarcoma of the liver.	
Arsenical medicinals (Fowler's Solution)	27 cases exposed to arsenic either via arsenical drugs or via occupation	Sommers and McManus (1953)	Case reports	Skin carcinomas were reported in all cases; visceral cancers were reported for some of the cases.	
Arsenical medicinal	Male patient	Nurse (1978)	Case report	Adenocarcinoma of the kidney	Patient treated with a variety of other drugs before developing kidney cancer.

TABLE 7-1. (continued)

Media	Study Population	Author(s)	Type of Study	Results	Highlights and Deficiencies
Arsenical medicinal	2 male patients 1 female patient	Knoth (1966)	Case reports	Female developed mammary carcinoma and skin cancer; 1 male patient developed a reticulosarcoma of the glans penis; 1 male developed skin cancer.	
Arsenical medicinals, occupational exposure, and air (occupational) exposure	16 vintners who were arsenical pesticide users; patient who took arsenical medicinals	Braun (1958)	Case reports	Skin and visceral cancers were reported among the vintners; skin and lung cancers were reported for one patient taking an arsenical medicinal; skin cancer was reported for the other patient who took an arsenical medicinal.	
Arsenical medicinals (Fowler's Solution)	2 male patients	Morris et al. (1974)	Case reports	One patient developed skin pigmentation, skin tumors, carcinoma of the larynx, and a probable bronchial carcinoma; the other developed skin pigmentation and keratosis. Both developed noncirrhotic portal hypertension.	
Arsenical medicinal (Fowler's Solution)	Female patient	Prystowsky (1978)	Case report	Woman developed nasopharyngeal cancer; also developed palmar and plantar keratosis.	
Arsenical medicinals (Fowler's (Solution)	4 male patients and 1 female patient	Popper et al. (1978)	Case reports	The cases developed angiosarcoma of the liver.	
Arsenical medicinal (Fowler's Solution)	1 male patient	Lander et al. (1975)	Case report	The patient developed angiosarcoma.	

TABLE 7-1. (continued)

Media	Study Population	Author(s)	Type of Study	Results	Highlights and Deficiencies
Arsenical medicinal (Fowler's Solution)	1 male patient	Roat et al. (1982)	Case report	The patient developed both angiosarcoma and skin cancer.	
Arsenical medicinal (Fowler's Solution)	7 male patients and 1 female patient	Falk et al. (1981a)	Case reports	The cases developed angiosarcoma.	
Wood preservative	Wood treaters in Hawaii	Gilbert et al. (1983)	Cross-sectional and cohort	No association of arsenic exposure with cancer mortality or morbidity was found.	The sample size was small (only 88 in the study cohort and 61 in the controls in the cross-sectional study; 125 in the mortality study; 182 in the morbidity study).

and Vahter, 1979; WHO, 1981; Tseng, 1977; Sunderman, 1976). This appears to be the case for medicinal (Neubauer, 1947), environmental (Tseng et al., 1968), and occupational (Roth, 1958; Braun, 1958) exposure. The time lag between initiation of exposure and occurrence of skin cancer has been reported to range from 6 to 50 years for arsenical medicinally-induced skin cancer. The minimal latency period for skin cancer in the most reliable epidemiologic study of arsenic-contaminated drinking water was reported to be 24 years.

The amount of data on the histological classification of lung tumors associated with occupational arsenic exposure is limited. Newman et al. (1976) report that arsenic-associated lung cancers are usually the poorly differentiated type of epidermoid bronchogenic carcinoma. These investigators studied worker groups with diagnosed lung cancer in copper-mining and smelting communities in Montana. Of 25 smelter workers, 4 had well-differentiated epidermoid carcinoma, 10 poorly differentiated epidermoid carcinoma, 7 small-cell undifferentiated epidermoid carcinoma and 3 acinar-type adenocarcinoma. Copper miners and "non-copper" control individuals had lung cancer profiles which were similar to each other.

The time period between initiation of exposure and the occurrence of arsenic-associated lung cancer was found in a couple of studies to be on the order of 35-45 years (Lee and Fraumeni, 1969). Recently, a latency period of <20 years was reported by Enterline and Marsh (1980; 1982) based upon their studies of copper smelter workers in Tacoma, Washington. Tokudome and Kuratsune (1976) found that the latent period for lung cancer ranged from 13 to 50 years.

The association of other visceral cancers with arsenic exposure has been noted in a number of reports and has been reviewed elsewhere (WHO, 1981; Arsenic. NAS, 1977; NIOSH, 1976; IARC, 1973). For example, hemangiosarcoma of

REC 5063

the liver, a rare form of cancer, has been diagnosed in workers exposed to arsenic and in non-occupationally arsenic-exposed individuals (Roth, 1958; Regelson et al., 1968; Lander et al., 1975; Falk et al., 1981a and b; Roat et al., 1982). Morris et al. (1974) have postulated that the peculiar hepatic fibrosis associated with arsenic-induced portal hypertension is a precursor state for subsequent progression to hepatic angiosarcoma. Popper et al. (1978) have noted that the hepatic fibrosis and hypertension seen in humans with Thorotrast, vinyl chloride or arsenic exposure are also induced by agents which presumably also have a role in hepatic angiosarcoma.

Other cancers noted in arsenic-exposed subjects include: lymphomas and leukemia (NIOSH, 1976; Ott et al., 1974); renal adenocarcinoma (Sommers and McManus, 1953; Nurse, 1978); and nasopharyngeal carcinoma (Prystowsky et al., 1978).

Pelfrene (1976) has criticized the reports of internal malignant neoplasms associated with arsenic exposure on the basis of the relative rarity of their detection in large-scale studies of chronic arsenic exposure such as that of Tseng (1968, 1977). More recently, Reymann et al. (1978) reported on a study of a group of 389 patients who took arsenic medicinally in the 1930s. An excess of internal cancers was not observed in the total cohort when compared with the expected incidence of malignant internal neoplasms based on the Danish Cancer Registry. The size of the cohort was probably too small to have detected an increase, however.

7.1.2 Epidemiological Aspects of Human Arsenic Carcinogenesis

7.1.2.1 Cancer of the Lung--A large number of reports are available on possible associations between occupational exposure to arsenic and cancer of the respiratory system. As is common in studies of this type, exposure data are very uncertain and the arsenic exposure is not always clearly defined regarding the physicochemical properties of the arsenic compounds. The picture is often

REC 5064

confused by simultaneous exposure to other agents, especially sulfur dioxide and metals. Data on smoking are often lacking or incomplete.

An excess mortality in respiratory cancer has especially been noted among workers engaged in the production and usage of pesticides, and among smelter workers.

In 1948, Hill and Faning presented data on proportional mortality rates among British workers exposed to a mixture of ingredients--including sodium arsenite, powdered sulfur and soda ash--used in the manufacture of a sheep-dip powder. Between 1910 and 1943, 75 deaths had occurred among workers in the sodium arsenite factory and 1,216 deaths had occurred among workers in the same area but without known exposure to arsenic. Proportionate mortality analysis showed that of the deaths among factory workers, 29.3 percent had died from cancer, whereas the corresponding figure for the other workers was 12.9 percent. The excess in cancer deaths among the factory workers was mainly due to an excess in lung cancer, 31.8 percent of all cancer deaths compared with 15.9 percent; and in skin cancer, 13.6 percent compared with 1.3 percent.

Among the factory workers, chemical workers, who were the workers most closely associated with arsenite production, had a higher proportion of cancer deaths than did the factory workers as a group. Furthermore, all lung cancer deaths had occurred among the chemical workers.

Arsenic in the air of the sodium arsenite factory was determined in 1945-46 (Perry et al., 1948) and concentrations up to 4 mg As/m^3 were found by sampling for 10 minutes. No data were given on the age of the deceased, and smoking habits were not recorded. The data do not allow any conclusions about exposure before 1943. Nevertheless, this study indicated that there might be an increased risk for respiratory cancer in the manufacture of arsenic-containing pesticides, and studies in two United States plants have given further support.

Ott et al. (1974) studied the mortality of workers in one of these two chemical plants. From 1919 to 1956 one unit formulated and packaged insecticides containing arsenic in the form of lead arsenate, calcium arsenate, copper acetoarsenite, and magnesium arsenate. During this period, the proportions of the different compounds varied. The main product was lead arsenate. The size of the workforce was about 30 in 1928 and 100 in 1948. Turnover was high with less than 25 percent of the men remaining with the unit for more than one year. Arsenic concentrations in air in 1943 were between 0.18 and 19 mg As/m^3 in the packaging area; in 1952 concentrations were 1.7-40.8 mg As/m^3 and 0.26-7.5 mg/m^3 in the drum dryer area and packaging area, respectively. By combining job classifications and air arsenic data, four exposure classifications were obtained with estimated arsenic exposures (8-hr TWA) of 5, 3, 1, and 0.1 mg/m^3. The total dosage was then calculated for each individual by multiplying air levels with the number of days at work and assuming that 4 m^3 were inhaled during a working day.

Mortality was studied by analysis of proportionate mortality and by a retrospective cohort analysis. Nearly 2,000 employees in the factory had died between 1940 and 1972. One hundred seventy-three were identified as having worked one or more days in the arsenical production unit and who then either worked for the company until death or died after retirement.

Ott et al. (1974), after adjusting for age and year of death, compared the differences in proportionate mortality between the study group and the controls. Among the exposed, respiratory cancer accounted for 16.2 percent of the deaths compared with 5.7 percent in the controls ($p < 0.001$). There was also a significant increase ($p < 0.05$) in deaths from lymphatic and hematopoietic cancers, except for leukemia. Table 7-2 shows the observed-to-expected ratios for respiratory cancer in relation to exposure. (In the original table, dosage estimates were based on 4 m^3 inhaled per 8 hr and expressed as the natural logarithms.

†n = 173, 138 workers had less than one year of exposure.

*Number in brackets shows respiratory cancer deaths in workers exposed less than one year.

Source: Modified from Ott et al. (1974), and Blejer and Wagner (1976).

In the present table, dosage is expressed in mg and is based on 10 m^3 inhaled air.) There is no tendency towards a dose-response relationship at total exposures from 105 to 3890 mg, but a sharp increase is noted at higher dosages. Furthermore, Blejer and Wagner (1976) reported that of the 173 deaths, 138 had occurred among workers with less than one year of exposure. In that group, 16 deaths were due to respiratory cancer. As seen in Table 7-2, 15 of those deaths occurred in the six groups with average total exposures estimated to be from 105 to 3890 mg. There are no quantitative data on other compounds that these workers might have been exposed to during their total time with the company; however, it is known that in addition to the arsenic-containing insecticides, the plant processed and packaged several other products, the most important of which were powdered sulfur and dry lime sulfur.

The retrospective cohort analysis was based on a roster of 603 workers who had worked for at least one month in the actual unit between 1940 and 1973. Workers leaving the company before retirement as well as workers who had been exposed to asbestos were not included in the analysis. It was stated that virtually all men with at least one year of exposure had been identified. Person-years, by 10-year age groups, for five calendar year groups were calculated and expected number of deaths were calculated by using United States white male mortality data. Table 7-3 shows that by this analysis a significant increase ($p < 0.01$) in deaths due to respiratory cancer was found among exposed workers. There was also a significant increase ($p < 0.01$) in the number of deaths due to malignant neoplasms in lymphatic and hematopoietic tissues, except leukemia.

A chemical plant in Baltimore was the subject of two studies concerning the working environment and one study concerning the outer environment. This plant started producing arsenic acid in the early 1900s and in the early

Source: Ott et al. (1974).

1950s production of arsenical pesticides started. Lead arsenate, calcium arsenate and sodium arsenate were among the compounds produced. Production terminated in 1974 (Matanoski et al., 1976). The plant also produced chlorinated hydrocarbons and organic phosphates. Data on air concentrations of arsenic are lacking.

In the first study, Baetjer et al. (1975) reported on both the proportionate mortality and age-specific death rates of workers who had retired between 1960 and 1972 and generally had at least 15 years' employment. Seventeen of 22 deaths among male white workers and two of five among female workers were due to malignant neoplasms. The female deaths did not appear to be related to occupational exposure, whereas, the male deaths did. Of the 17 malignant neoplasms in males, 10 were in the respiratory tract, 3 were lymphosarcomas, and the remaining 4 were of other tissues. The proportionate mortality analysis, based on mortality data for the city of Baltimore, showed an observed/expected ratio of 6.58 for respiratory cancer ($p < .05$) and 15.79 for cancer of the lymphatic and hematopoietic system ($0.1 < p < 0.05$). The age-specific death rate analysis showed that deaths from respiratory cancer were 16.67 times the expected, and, that for lymphosarcomas, the observed number was 50 times that of the expected number. The authors reported that observed and expected rates for non-cancer deaths did not differ significantly ($p < 0.05$).

In a second study (Mabuchi et al., 1979), a follow-up was made of workers employed from 1946 to 1974. Since exposure data were lacking, an attempt was made to classify workers according to exposure to arsenicals and non-arsenicals. A roster of 3,141 workers was obtained. Since 2,189 workers had been employed for less than 4 months, a 20 percent random sample was drawn from that population and together with the remaining 952 workers constituted the study popula-

tion: 1,050 males and 343 females, mainly white. Exposure assessments were made, and the workers were categorized into one of six exposure groups.

Of the study population, 240 had died: 197 males and 43 females. Expected deaths were calculated from the city of Baltimore statistics. The observed/expected ratios for lung cancer were analyzed by exposure, year of first employment, and duration of employment. A statistically significant increase in lung cancer mortality (SMR = 336, $p < 0.05$) was found among "predominantly arsenical production" workers. There was a clear lung cancer mortality dose response among these workers by duration of exposure. Those employed 15-24 years and 25+ years both had statistically significant ($p < 0.05$) lung cancer SMRs (1365 and 2750, respectively). Interestingly, statistically significantly elevated SMRs were only found in "predominantly arsenical production" workers, but not in workers engaged entirely in arsenical production. Further analysis revealed that the proportion of workers engaged entirely in arsenical production for 5 years or more was relatively low (1 percent), while the proportion of workers exposed predominantly, but not entirely, to arsenic for 5 years or more was much higher (29 percent). This difference in duration of exposure may have accounted for the absence of excess lung cancer mortality among the workers engaged entirely in arsenical production. Data on smoking were not obtained.

Occupational exposure to arsenical pesticides has been common among vintners and agricultural workers. Exposure has mainly been to lead arsenate. In a study of orchard workers who used lead arsenate in the Wenatchee Valley in the state of Washington, Nelson et al. (1973) found a deficit of lung cancer mortality for the period 1938-68 when compared with mortality for the state of Washington.

Because the results of this study were at variance with previous evidence on the long-term effects of arsenic exposure, NIOSH reviewed data from other

sources and used alternative procedures in an attempt to verify the findings. Analysis of respiratory cancer mortality data by occupational category for the state of Washington for the period 1950-71 found that orchardists had 19 percent more deaths from respiratory cancer than expected. An analysis of cancer mortality rates for 1950-69 for the counties comprising the locale from which the orchardist sample was drawn by Nelson et al. found that males had a 7 percent higher respiratory cancer rate than expected among males. The county from which most of the orchardists were drawn had a 31 percent excess ($P < 0.01$) of lung cancer mortality. Thus, it was NIOSH's (1975) conclusion that the Nelson et al. report did not accurately depict the cancer experience of persons exposed to lead arsenate spray in the Wenatchee Valley.

Several studies in Germany indicate that workers exposed to arsenic trioxide when spraying vineyards had a high mortality in cancer, especially lung cancer. In one report (Roth, 1958), it was stated that of 47 autopsies among vintners with chronic arsenic intoxication, 30 (64 percent) were due to cancer, and 18 to lung cancer (60 percent of all cancer deaths). The author did not state how the cases were selected, nor were controls used in the study.

Gilbert et al. (1983) studied a group of 182 workers in Hawaii exposed for at least 3 months during the period 1960-1981 to the wood-treating chemicals chromated-copper-arsenate (CCA), pentachlorophenol (penta), tributyl tin oxide (TBTO) and lindane. The study was divided into two parts: (1) a cohort comparison study of 88 workers and 61 controls and (2) a historic prospective study which consisted of a morbidity and a mortality analysis of the entire cohort.

In the cohort comparison study, 61 controls were matched on the basis of age, sex, race, level of physical activity, and weight to 88 wood treatment

REC 5072

workers who were "qualified and agreed to participate in the study." Controls were recruited from among the membership of carpenters', ironworkers', masons', plumbers', and stevedores' unions and from the names of friends and relatives referred to the study by participating members of the occupational cohort. Fourteen of the controls were reported to be carpenters and 13 of them had had exposure to either CCA or penta or both. Their urine arsenic levels, however, were reported not to differ significantly from those of other controls. The exposed group and the control group were each given a comprehensive health examination consisting of a questionnaire and clinical and laboratory tests including analysis of a urine sample for penta, arsenic, copper, chromium, and tin levels. Only penta was found to be significantly elevated in the urine of the exposed group over that of the controls. The authors reported that there were no "clinically significant" differences between the exposed group and the controls. No significant differences were found between the wood treaters and controls with respect to educational level, smoking history, or alcohol consumption.

The historical prospective study identified three cases of cancer, one by means of the questionnaire in the cross-sectional study and the other two by means of the Hawaii Tumor Registry. One of the cancer cases was a bladder cancer case; the other two were colorectal cancer cases. For the mortality analysis, the vital status of 125 of the 182 workers (69 percent) was able to be determined. Of these 125, six deaths occurred, five from cardiovascular disease, the other from an unknown cause. The authors calculated that eight deaths would have been expected in this group, three of which would have been from cancer. The authors did not state the basis of the expected number of cancer deaths.

There are limitations in the study design and sample size of this study which make the results with regard to the evaluation of a cancer risk among

the wood treaters inconclusive. A cohort comparison study on the basis of a single medical examination is an inappropriate approach to determine if a cancer risk exists in the wood treater group, particularly when the group consists primarily of persons who are currently employed as wood treaters (60 of 88 were current employees). Most persons who have developed cancer will either have died or left the work force. In addition, the sample size (88 current or former wood treaters and 61 controls) would have been too small to detect an excess cancer risk. Also, it should be noted that the inclusion in the controls of 13 carpenters who had been exposed to arsenic-treated wood certainly presents a potential bias, despite the fact that the authors claimed that the levels of arsenic in the urine of these 13 were not significantly different from those in other controls. In this regard it should be noted that no effort had apparently been made to restrict the intake of seafood or other foods or liquids, which might have elevated urine arsenic levels, prior to collection of the urine samples. The mean level of urinary arsenic in both the study group and in the controls was significantly ($P < 0.01$) higher than what the authors reported would be a normal level.

The historic prospective study also had limitations. Again, the sample size was too small to adequately determine whether an excess risk of cancer existed in the study cohort. Only 125 were included in the mortality study and only 182 were included in the morbidity study. Arsenic exposure via inhalation and ingestion is known to be associated with lung and nonmelanoma skin cancer, respectively. Nonmelanoma skin cancer is rarely fatal and thus, an excess risk of skin cancer would not have been detected in such a small mortality study. The Hawaii Tumor Registry, which was one of the primary sources of information used to identify cancer cases for the morbidity study, does not even report nonmelanoma skin cancer.

REC 5074

There is also a question of whether the authors had sufficiently allowed for a cancer latency period in their study. The authors did not indicate the length of follow-up of the cohort members. Some indication is provided, however, in the data reported by the authors on the length of employment of the 88 workers in the study cohort of the cohort comparison study. These workers were part of the population in the incidence and mortality studies. Of the 88 workers, 60 had worked 10 years or less and 80 had worked 15 years or less at the time of the physical examination in 1981. Twenty-two of the study cohort in the cohort comparison study were former employees. At the minimum, assuming that the workers had had no breaks in employment, 58 of 125 (46 percent) in the mortality study would have been followed for only 15 years or less and 38 of 125 (30 percent) would have been followed for only 10 years or less. In the morbidity study, if, again, no breaks in employment of the workers are assumed, 58 of 182 (32 percent) would have been followed for only 15 years or less and 38 of 182 (21 percent) would have been followed for only 10 years or less. In conclusion, this study is inadequate to conclude whether an excess risk of cancer exists in the wood treater population in Hawaii.

Occupational exposure to arsenic also occurs in smelters where exposure is predominantly to arsenic trioxide. Several studies have been done on mortality among workers at the copper smelter in Tacoma, Washington. Pinto and Bennett (1963) reported on the proportionate mortality of 229 workers from 1946 to 1960. Workers leaving the plant before retirement were not included. The proportionate mortality of the smelter workers was compared with that of males in the state of Washington in 1958. Of all cancer deaths, the respective proportions of lung cancer were 41.9 and 23.7 percent, respectively. The authors then classified the smelter workers according to arsenic exposure and did not find any difference between exposed and non-exposed. However, the "non-exposed" had elevated arsenic levels in urine, suggesting possible exposure.

More extensive studies have since been published, showing an increase in lung cancer among arsenic-exposed workers (Milham and Strong, 1974; Pinto et al., 1977; Pinto et al., 1978; Enterline and Marsh, 1980; Enterline and Marsh, 1982).

Milham and Strong (1974) examined county records from 1950 to 1971 to find the number of deaths due to respiratory cancer among county residents employed at the smelter. Expected number of cases were calculated for the smelter population by using the 1960 age-cause specific mortality statistics for white males in the United States. Forty deaths were observed and 18 were expected.

The two papers by Pinto et al. (1977, 1978) refer to the same study and the following is based on the 1978 paper. The cohort studied consisted of 527 men who were living pensioners on January 1, 1949 or who became pensioners before January 1, 1973. Complete job histories were obtained for 525 men. The average duration of employment was 28 years, ranging from 7 to 54 years and beginning in 1910. Death certificates were obtained for all 324 men who had died during the observation period (1949-1973). Expected numbers of deaths were calculated from statistics of the state of Washington.

An exposure index was constructed by using data on urinary levels of arsenic obtained in 1973. Mean urinary concentrations were calculated for 32 departments, and the individual exposure index was obtained by multiplying urinary arsenic level with years of work in a department. If an individual had worked in more than one department, the index values were added. By dividing the exposure index by the total number of years in the smelter, an index of intensity of exposure was obtained, i.e., the average urinary arsenic level. These indices were created to enable interdepartmental comparisons and did not reflect past exposure since air analysis in the 1930s to 1940s indicated

that exposure might have been 5-10 times higher at that time. It may have been still higher in 1910.

Data were also obtained on smoking habits from all men still alive and from relatives of men who had died since January, 1961. Table 7-4 (Pinto et al., 1978) shows that there was a significant increase ($p < 0.05$) in deaths from all causes, in cancer deaths in general, and, specifically, in deaths from respiratory cancer. Almost all of the excess mortality could be explained by the increase in lung cancers which could not be explained by smoking.

Table 7-5 shows respiratory cancer deaths in relation to exposure index (a value which reflects both the duration and intensity of exposure). An increase in SMR with exposure is seen. Table 7-6 shows that both duration and intensity of exposure contributed to the excess in respiratory cancer. As stated above, the urine values are relative and do not reflect the actual exposure.

It was also shown that the main excess occurred in ages 65-74 years, whereas at higher ages the lung cancer rate was closer to expected rates.

More recently, Enterline and Marsh (1980, 1982) conducted additional studies on workers at this same copper smelter in Tacoma. A cohort of 2802 males who worked a year or more during the period 1940-1964 was identified. Since a one-year work exposure was required for eligibility into the cohort, actual follow-up did not start until 1941 and extended through 1976. In the cohort, the vital status of 51 could not be verified, leaving 2751 persons. In that group, 1061 deaths had occurred. There was a significant increase in total cancer mortality which wholly depended on an increase in deaths from lung cancer. Arsenic exposure was estimated for each man on the basis of a representative average urinary arsenic level for workers in a given department. Using this representative value, an individual value was calculated for each

man for each year of employment in a given department, and a total exposure estimate per individual was made by summing values across all jobs and all years of employment.

This method of estimating exposure differed from earlier methods employed by Enterline and co-workers (Pinto et al., 1977, 1978) in that estimates of historic exposure, based upon simple linear interpolations and extrapolations of actual data from 1948-52 and 1973-75, were used to characterize exposure by department, rather than by 1973 urinary measurements. Use of this new method of analysis partially helped to eliminate exposure underestimates of workers employed in the early years of the smelter operation. However, the present method did not totally eliminate this bias because urinary arsenic levels were only determined for workers starting in 1948. For workers exposed prior to 1948 (approximately 80 percent of the present study cohort), urinary arsenic values for 1948-52 were assumed to apply. Furthermore, the average urinary arsenic level for some departments may have been based on only a few samples, thereby limiting the usefulness of the departmental average as a representative measure of any given worker's urinary arsenic level. The authors did note that in areas of the smelter where arsenic levels were reported to be high, workers tended to be measured more often for urinary arsenic. Thus, averages for those areas were, in fact, more representative.

Using this time-weighted measure of exposure, a life table method for accumulative dose, a 10-year lag period and a standard population of mortality rates in the state of Washington, the authors reported that SMRs for respiratory cancer ranged from 155 in the lowest exposure category to 246 in the highest category. Table 7-7 shows the relationship between the time-weighted estimates of arsenic exposure lagged 0 and 10 years and respiratory cancer. This relationship was much weaker than that previously reported by Pinto et al. (1977, 1978). Enterline and Marsh noted that results from the two sets of

studies were not totally comparable due not only to the differences in the exposure estimates noted above, but also to differences in follow-up periods. In earlier reports, the follow-up started after exposure stopped at retirement, whereas in the present study, follow-up started at various points in the work experience of the workers, allowing for follow-up and dose accumulation to proceed concurrently. When the authors analyzed a subsample of the present study cohort, consisting of 582 workers retired at age 65 and over (paralleling the experimental design of the earlier studies), a stronger dose-response relationship was, in fact, observed.

Table 7-8 shows the respiratory cancer deaths and SMRs by duration of exposure and time since first exposure. From Table 7-8, it appears that neither duration of exposure nor long latent periods made strong contributions to excess respiratory cancer. The authors suggested that this may have been due to the high SMRs observed shortly after termination of employment but not noted thereafter; thus, for workers with less than 10 years of exposure the

SMR is highest 10-19 years after date of hire; for workers employed 10-19 years, the SMR is highest 20-29 years after date of hire, etc. This high relative risk of lung cancer mortality in the decade following termination of employment, which essentially disappears in the following 20 years, prompted the authors to suggest that arsenic may be a promoter rather than an initiator. However, when the authors reanalyzed the data according to a method which followed workers only from the point of termination or retirement, both duration of exposure and intensity of exposure contributed more strongly to respiratory cancer mortality (Table 7-9). The difference in the two analyses led the authors to suggest that the weak dose-response relationship observed in the first analysis may have resulted from a tendency for workers in high-exposure jobs to leave employment more quickly than those in low-exposure jobs.

In studying the interactive effects of sulfur dioxide, the authors did not find significant differences in respiratory cancer incidence in two departments which both had high arsenic exposures (7500 $\mu g/m^3$) but differing SO_2 exposures, one having low to moderate exposures (520 ppm) and the other having essentially none. Because the respiratory cancer SMRs were quite similar in the two departments, the authors suggested that SO_2 exposure did not play an important role in respiratory cancer excess at that particular smelter.

In discussing their overall study results, Enterline and Marsh noted that, in this particular case, a dose response was not observed when dose was measured in terms of cumulative dose. The results seen in Table 7-8 suggest that short exposures seemed to have a disproportionately greater effect than long exposures and that effects of early exposure tended to diminish with time. Table 7-9 suggests that short high-intensity exposures may have a greater effect than longer-term, more low-level exposures. The fact that different results are obtained when different exposure/follow-up methods are

employed suggests that choice of experimental design has a possible influence on results. The possibility that some workers may have simply been more susceptible than others may also have accounted for the dose-response relationships observed in this study.

Because the authors suggested that the role of arsenic in the carcinogenesis process may have been as a promoter rather than an initiator, the significance of cumulative exposure to arsenic as a measure of dose would be questionable in regard to the induction of respiratory cancer as observed in this study. The role of arsenic as an initiator as well as a promoter cannot be ruled out, however. Until further research is done, the authors' conclusions from this study remain speculative.

Mortality of workers in a smelter in Magna, Utah, was studied by Rencher et al. (1977). Average hourly air concentrations of arsenic in 12 work areas were between zero and 22 mg/m^3 in 1975 (NIOSH, 1975). However, exposure before 1959 had likely been higher, since a processing of ore with a relatively low arsenic content began in that year. In the period 1959 to 1969, 965 deaths had occurred among all current or former employees, and death certificates were obtained for virtually all deceased. The proportionate mortality for smelter workers was compared with that for mine workers, concentrator workers, refinery workers, and office workers, and for the population above 20 years of age for the entire state of Utah in 1968. Among the smelter workers, 7 percent of the deaths were due to respiratory cancer, whereas the percentage for the other factory employees varied from 0 to 2.2 percent and was 2.7 percent for the state. Data on smoking were obtained for all smelter workers and for subsamples of the other employee groups and indicated that nonsmoking smelter workers had the same percentage of deaths from lung cancer as mine and concentrator workers who smoked. By applying lifetable methods, age-adjusted

death rates were obtained. For smelter workers, a death rate for lung cancer of 10.1 per 10,000 was obtained compared with 2.1 and 3.3 per 10,000 for mine workers and the state population, respectively. Causes of death were compared with a cumulative exposure index obtained by multiplying the number of days spent in each department by the average exposure level and then summing. The average exposure to arsenic as well as sulfur dioxide, sulfates, lead, and copper was found to be higher for the lung cancer cases than for other causes of death.

In addition to these studies, a large study by Lee and Fraumeni (1969) involving 8,047 white males was conducted at the Anaconda Copper Smelter in Montana from 1938 to 1956.* Data were obtained on time, place, and duration of employment for each individual, all subjects having worked at least 12 months in the smelter during the indicated study period. Follow-up was from 1938 to 1964. Death certificates were obtained, and the lifetable method was used to compute the expected number of deaths, using mortality rates of the state of Montana. The smelter workers were classified into 5 cohorts, based on total years of smelter work and the time period in which the years were worked: (1) 15 or more years worked before 1938; (2) 15 or more years worked between 1938 and 1963; (3) 10-14 years; (4) 5-9 years; and (5) 1-4 years. An attempt was also made to classify the workers according to exposure to arsenic and sulphur dioxide. Exposure to arsenic for more than 12 months had occurred among 5,185 men. These workers were divided into three groups; heavy, medium, and light exposures. This division was based on exposure times and place at work. Arsenic concentrations in air were primarily determined from a

*While the original Lee and Fraumeni study reported on the mortality experience of male smelter workers in unidentified states, subsequent analyses of these workers indicate that they were employed solely at the Anaconda smelter in Montana.

REC 5086

TR 1771

1965 survey by Public Health Service officials (NIOSH, 1975). These air data are shown in Table 7-10.

According to a former public health official associated with this survey, actual measurements were collected during two different periods--one in 1965 and one "about five to six years earlier"--and at several locations within given departments (Archer, 1983; personal communication). It is impossible, however, to determine how the values listed in Table 7-10 are distributed over these different time periods and locations. Further, it is also impossible to determine the number of hours sampled at a given location. Therefore, the arithmetic means used by Lee and Fraumeni to characterize heavy, medium and light exposures can only be viewed as very rough estimates of arsenic exposure, their primary value being in their relative scale of measurement.

In Table 7-11 it is seen that heavy and medium exposures resulted in significant increases in SMR for respiratory cancer. The SMR was highest (800) in workers belonging to cohort 1 (more than 15 years of smelter work before 1938), and then decreased to 263 among workers with 1-14 years of smelter work. Among the workers with light exposure, the SMR was 250, 310, and 214 in cohorts 1, 2, and 3-5, respectively. Among the smelter workers with less than 12 months' exposure to arsenic, the SMR was 286.

Lee and Fraumeni also looked at factors that possibly had confounding effects on their study results. Smoking histories were not recorded; however, based upon information obtained from other studies, Lee and Fraumeni concluded that smoking alone could not have accounted for the excess respiratory cancer mortality of the magnitude observed in their study.

In contrast to smoking, the authors did note a positive relationship between exposure to sulfur dioxide and respiratory cancer mortality; however, they found it difficult to separate the relationship of arsenic from sulfur

dioxide. Most of the work areas having heavy arsenic exposure were also areas having medium sulfur dioxide exposure; conversely, all work areas with heavy sulfur dioxide exposure were areas of medium arsenic exposure. The authors did note, however, that persons with the heaviest exposure to arsenic and moderate or heavy exposure to sulfur dioxide were those most likely to die of respiratory cancer in this particular instance.

Since the Lee and Fraumeni study, additional research has been conducted on the employees of the Anaconda smelter. Lubin et al. (1981) studied 5403 of these employees. These workers had all been employed for 12 months or more between January 1, 1938, and December 31, 1956, and were known to be alive as of December 31, 1963. Essentially, this cohort was equivalent to the surviving members from the Lee and Fraumeni cohort.

Exposure was from date hired to December 31, 1963; follow-up was from 1964 to 1977. Classification of exposure categories was similar to that of Lee and Fraumeni. However, unlike the study of Lee and Fraumeni, a cumulative arsenic exposure index was calculated for each worker. This index was derived by, first, weighting the three exposure categories and then multiplying the number of years an individual worked in a given category by this weight and summing over categories. The weights were derived from mean airborne dust concentrations taken during 1943 to 1958, which averaged 11.3, 0.58 and 0.29 mg As/m^3 in the respective heavy, medium and light categories. These values differed from those used by Lee and Fraumeni to group departments (Table 7-9). It should be noted that the exposure estimates used by Lee and Fraumeni were based upon more recent monitoring data primarily collected in 1965. Lubin et al. reduced weights in the heavy category by a factor of 10 in order to account for the wearing of respirators as was observed "at least in recent years." SMRs were calculated by comparisons to U.S. white males.

REC 5090

The mortality experience of workers during the years 1964 to 1977 was similar to that of the workers studied by Lee and Fraumeni during the period 1938-1963. Excess deaths from respiratory cancer corresponded to areas of highest arsenic levels. The authors noted an overall strong gradient in risk associated with the indices of cumulative arsenic exposure. However, the authors also noted that this gradient was less clear when weighting of the high-exposure category was reduced ten-fold to account for respirator usage. According to Welch et al. (1982), however, respirator usage was not common prior to 1964.

Some study differences were noted by Lubin et al. between their respective study and that of Lee and Fraumeni. Differences in excess respiratory cancer--65 percent in the more recent period versus a three-fold excess in the earlier period--were partially attributed to differences in respiratory cancer rates observed between the two comparison populations. Respiratory cancer rates in the general populace have increased in recent years; therefore, comparisons to recent populations will produce lower relative risks than comparisons to past general populations in which the rates of respiratory cancer were lower. The authors also noted that the comparison populations differed in composition. Lee and Fraumeni used white males in the state of Montana as their standard population, whereas Lubin et al. used U.S. white males. As noted in this study, as well as elsewhere (Welch et al., 1982; Higgins et al., 1982), death rates for specific causes of death (inclusive of respiratory cancer) have been reported to be lower in Montana. Finally, the authors suggested the possibility that individuals most susceptible to lung cancer contracted the disease in the earlier period and were, thus, lost to the study follow-up due to death.

In looking at SO_2 exposures, the authors were unable to totally separate the possible interactive effects of SO_2 with arsenic. However, they did note

that after controlling for arsenic, no significant increase in mortality could be associated with heavy or medium SO_2 exposures, whereas the association with arsenic exposure persisted after controlling for SO_2. This finding is consistent with that of other researchers studying smelter populations (Enterline and Marsh, 1982; Welch et al., 1982; Higgins et al., 1982).

In an update of the earlier study co-authored with Fraumeni, Lee-Feldstein (1983) observed the mortality experience of the same Anaconda workers (with the exception of two women) from 1938 to 1977. The workers (8045) were assigned to one of five cohorts on the basis of total years of employment. Cohort 1 worked 25+ years; cohort 2, 15-24 years; cohort 3, 10-14 years; cohort 4, 5-9 years, and cohort 5, 1-4 years. SMRs were calculated by comparison to the combined white male populations in the states of Idaho, Wyoming and Montana.

Of the thirteen specific causes of death considered, tuberculosis, digestive and respiratory cancer, vascular lesions of the CNS, diseases of the heart, emphysema, and cirrhosis of the liver showed a significant excess of observed deaths over that expected; however, only excesses in respiratory cancer showed a positive gradient with length of employment when comparing cohorts 1 through 5. The ratio of observed to expected mortality from respiratory cancer was approximately 5.1, 4.5 and 2.3 in the heavy, medium and light arsenic-exposure groups, respectively. This was in accord with the earlier results of Lee and Fraumeni, except that the ratio of observed respiratory cancer deaths to that expected in the heavy exposure category in the earlier study was 7.

Brown and Chu (1983c) discussed the Lee-Feldstein (1983) data with regard to its implications on the multistage theory of cancer. They indicated that analysis of the data suggests that arsenic acts as a late-stage carcinogen

because: (1) there was an increasing excess lung cancer mortality risk with increasing age at initial exposure, and (2) the excess mortality was independent of time after exposure stopped.

Higgins et al. (1982) and Welch et al. (1982) reported on a sample of 1800 workers at the Anaconda smelter. Compared to the 8047 workers studied by Lee and Fraumeni, this cohort of 1800 workers included all the workers originally designated in Lee and Fraumeni's heavy exposure category (277) and a random sample (20 percent) of the remaining known workers. The date of entry into the study cohort ranged from 1938 to 1956, providing the individual had one year of work experience. Unlike other studies on these workers, smoking histories on the 1800 workers were obtained either by direct questioning or by proxy respondent. SMRs were based on comparisons to white males both in the state of Montana and the United States.

From industrial hygiene records for the period 1943 to 1965, estimates of airborne arsenic concentrations within 35 smelter departments were provided. A total of 818 samples were collected from 18 departments and departmental averages were calculated from these measurements. The remaining 17 departments were estimated by analogy with those that were known. The departments were then grouped into four categories in which arsenic exposure was characterized as low ($<100\ \mu g/m^3$), medium ($100\text{-}499\ \mu g/m^3$), high ($500\text{-}4999\ \mu g/m^3$) or very high ($>5000\ \mu g/m^3$).

Workers were assigned to these categories based upon estimations of both time-weighted average (TWA) arsenic exposure levels and ceiling levels. TWA values were individually calculated based upon the time that a worker spent in a given department and the average arsenic concentration estimated for that department. This quantity was summed across all departments the individual worked in and was divided by total time worked to yield a TWA. TWA arsenic

exposures were calculated at entry into the study cohort and at the beginning of January, 1964, corresponding to the end of the follow-up period used by Lee and Fraumeni. TWA differences between these two periods could have increased, decreased, or remained the same depending on the work history of an individual worker. In contrast, ceiling levels were defined as the highest level to which an employee was exposed for a period of 30 days or more. Ceiling levels were calculated at entry into cohort, at the beginning of 1964 and at the beginning of 1978. Unlike a TWA value, a worker's ceiling level could only increase or remain the same from point of entry into the cohort.

Data were analyzed according to five different exposure/follow-up methods which varied in the amount of overlap allowed between exposure and follow-up periods. Method I, the primary method used by the authors, included each worker's arsenic exposure up to the date he entered the cohort. Follow-up was from entry to 1978; thus, there was no overlap of the two periods. Method IV--exposure from date hired to 1964, follow-up from 1964 to 1978--also had no overlap. Methods II and V had complete overlap--exposure from date hired to 1964, follow-up from 1938 to 1964 and exposure from date hired till termination, follow-up from 1938 to 1978, respectively. Method III had partial overlap--exposure from date hired to 1964, follow-up from 1938 to 1978. Except where specifically noted, results were given according to Method I.

The results of the study supported the thesis that exposure to arsenic was strongly related to respiratory cancer mortality in workers at the Anaconda smelter. SMRs for the total cohort for all causes of death were identical when compared to either the state of Montana or U.S. white males (both SMRs = 133, significant at 0.01 level); however, SMRs for specific causes were somewhat higher when compared to Montana males than when compared to U.S. males. Exposure to arsenic appeared to be the principal factor in the observed

increased risk for respiratory cancer, the study cohort having 3 times the expected death rate for white men living in Montana. Exposure to other occupational contaminants, such as sulfur dioxide and asbestos, did not appear to account for respiratory cancer excess, while smoking explained only a small fraction of the excess.

Of particular note were the differing respiratory cancer results obtained under the two categories of arsenic exposure (Tables 7-12 and 7-13). The SMR for men in the lowest TWA category was elevated, although not significantly so, whereas the SMRs in the other TWA categories were significantly elevated. Mortality for respiratory cancer by ceiling arsenic exposure showed that SMRs were only signficantly elevated in the high and very high categories, whereas they were close to expectation in the two lower exposure categories. Date of hire showed a definite relationship to mortality from respiratory cancer. Workers who were employed in the early years of the smelter operation--from 1884 to 1938, but particularly prior to 1923, when a selective floatation process which markedly improved fume and dust recovery was introduced--had higher SMRs, indicating that the overall higher arsenic exposures in the early years were associated with higher death rates from respiratory cancer. Age at hire did not seem to have a confounding effect, although the authors did note that the SMRs for respiratory cancer showed more fluctuation with age than did all causes of death.

Tables 7-14 and 7-15 show comparisons of TWA and ceiling respiratory cancer mortality as analyzed by the different exposure/follow-up methods. The authors noted that, while there was some variation in the SMRs derived from the different methods, the same basic pattern of increasing respiratory cancer SMRs with increasing TWA and ceiling arsenic exposures could be seen for each method. The authors indicated that none of the exposure/follow-up methods found a significantly ($P < 0.05$) increased respiratory cancer risk for ceiling level

categories less than 500 $\mu g/m^3$ of arsenic (Table 7-15). For the respiratory cancer SMR analysis by TWA exposure, a significantly ($P < 0.05$) elevated SMR was not found in the lowest dose category. In the 100-499 $\mu g/m^3$ TWA exposure category, there was a significantly ($P < 0.05$) elevated respiratory cancer SMR (Table 7-14). The respiratory cancer SMR in this category would not have been significant, however, if those respiratory cancer deaths with <500 $\mu g/m^3$ ceiling arsenic exposure had been excluded from the analysis. The authors concluded that if a worker in the study had not been exposed to <500 $\mu g/m^3$ ceiling level, he would have had little, if any, excess cancer risk.

A number of criticisms have been made of this study (48 FR 1864), a few of which bear mentioning at this point. The representativeness of the exposure estimates as they relate to overall exposure conditions in the smelter and specifically to the cohort's TWA and ceiling exposures has been criticized. The authors noted that individual worker exposure estimates, based upon area measurements rather than personal samples, would not likely have great precision. Furthermore, estimates of analogy--as in 17 of the departments--weaken the reliability of overall exposure estimates, although areas that were thought to be "problem" areas of high exposure were areas that were generally measured. The extent to which respirator usage was an effective protective measure is also unknown. In interviews with former workers, however, indications were that the use of respirators was not widespread or regular during the period prior to 1964. Collectively, the authors stated that exposure estimates probably tended to affect results such that exposure values were underestimated from 1884 to 1938, were reasonable for 1938 to 1964, and were overestimated for the period after 1964.

The authors found that workers who had not experienced a ceiling level of 500 $\mu g/m^3$ of arsenic did not have an elevated risk of lung cancer. However, the number of lung cancer deaths that could be predicted using a linear dose-

response model (see Section 7.3.1) in the group of workers with <500 $\mu g/m^3$ arsenic ceiling exposure would not be significantly different than the number of lung cancer deaths actually found. This was determined using the linear risk model (Section 7.3.1) and data obtained from Higgins and made available by Consultants in Epidemiology and Occupational Health (1982) on the cross-tabulation of the number of workers in cumulative and ceiling exposure categories. Higgins et al. are presently undertaking a study of the entire Anaconda cohort; however, results of this study will not be forthcoming until late 1984.

In foreign smelters, an excess in lung cancer mortality has also been found. The Rönnskär smelter in Sweden, which has been processing arsenic-rich ores since the 1920s, has been the subject of several studies. Axelson et al. (1978) conducted a case-control study of mortality from respiratory cancer in relation to employment at that smelter. In the parish surrounding the smelter, 369 deaths have been recorded in the registers for men aged 30-74 years during the years 1960 to 1976. Causes of death were obtained in all cases. Smoking habits were obtained from medical files. Cases were defined as subjects who died of malignant tumors of the lung, other cancers, cardiovascular disease, cerebrovascular disease, and cirrhosis of the liver. The control group was made up of persons from the same parish who died from causes other than the above, excluding 44 persons with diabetes, mental deficiency and unclear diagnoses. Attempts were made to assess exposure and four exposure groups were constructed, based on intensity and duration of exposure and time between initiation of exposure and death. It was found that occupational exposure to arsenic was associated with a significant increase in deaths from lung cancer. For the three exposure groups with at least 3 months of exposure occurring 5 years

prior to death, the lung cancer mortality ratio was 4.6. In these groups, there was an increase with exposure intensity. For the fourth group in which either persons were not exposed or the first exposure was for a period less than 3 months and/or death occurred within 5 years of this first exposure, a risk of respiratory cancer was not found.

Other agents, including sulfur dioxide, did not seem to be associated with lung cancer in this study. In 83 percent of the exposed lung cancer cases there was a history of smoking. A study of smoking habits by Pershagen (1978) showed that the excess lung cancer mortality could not be explained by smoking habits.

Because a high lung cancer mortality rate was noted among males in Saganoseki-machi, Japan, for the period 1967-69, Kuratsune et al. (1974) did a case-control study of lung cancer cases in that town. The nineteen cases of lung cancer for the period 1967-69 were compared with nineteen controls randomly selected from deaths of diseases other than cancer of the lung, skin, or bladder for the 1967-69 period. Smoking and drinking habits, residential and occupational histories, and exposure to atomic bomb radiation were the factors compared. Fifty-eight percent of lung cancer cases were found to be former smelter workers vs. 15.8 percent in the controls ($p < 0.01$). The relative risk was reported to be 9.0 (confidence limits not reported). No difference was found between the cases and controls for smoking habits, residential history, drinking habits, or atomic bomb radiation.

Tokudome and Kuratsune (1976) did a cohort study of 2765 male workers, including 839 copper smelter workers at the metal refinery in Saganoseki-machi, Japan. Deaths which occurred between 1949 and 1971 were analyzed in the

study. The expected number of deaths was calculated using mortality data for Japanese males. A significantly increased mortality was noted for lung cancer (SMR = 1189; observed = 29; expected = 2.44; $p < 0.01$) and colon cancer (SMR = 508; observed = 3; expected = 0.59; $p < 0.05$). A dose response was demonstrated between lung cancer mortality and the degree of exposure measured by length of employment and level of exposure. A very high excess mortality from lung cancer (SMR = 2500; 10 observed; 0.4 expected; $p < 0.01$) was found among smelter workers who had worked in the heaviest exposure category and who had been employed over 15 years before 1949. The latent period in this study ranged from 13 to 50 years.

Studies have also been performed to see if there is any increase in lung cancer among residents in areas surrounding smelters. Lyon et al. (1977) compared the incidence of lung cancer and lymphoma in Utah residents from 1970-1975 in relation to the distance of these residents from a smelter and found no association. It should be noted that distance from the smelter was based on address at the time of diagnosis; nothing regarding the length of time lived near the smelter was factored into the analysis. Furthermore, use of lymphoma cases as controls is questionable since lymphomas may also be associated with arsenic (Ott et al., 1974). Thus, the conclusion of the study that there was no association between lung cancer and distance from the smelter is questionable.

In a more recent study, Rom et al. (1982) compared lung cancer with breast and prostate cancer in residents living near a non-ferrous smelter in El Paso, Texas. The study period ranged from 1944-1973. Similar to methods used by Lyon et al. (1977), comparisons were made in relation to distance from the smelter. Breast and prostate cancer were chosen as control cancers because they have no known association with arsenic exposure. The authors reported

that the distribution of lung cancer cases (575) and control cancer cases (1490) was roughly the same for the different distances studied. No association between lung cancer and distance from the smelter was found, nor were there any associations for race, age or sex. However, the authors did note that they were unable to control for such factors as smoking, occupation and migration and were unable to obtain environmental exposure measurements over most of the years studied.

In Montana, the studies by Newman et al. (1976) showed that there was an increase in the incidence of lung cancer among men in cities where copper smelters are located. In one of the cities there was also an increased incidence of lung cancer among women. It was not stated to what extent occupational exposure had caused the increase, and there was no control for smoking.

In the Blot and Fraumeni study (1975), the cancer mortality in 71 counties with smelters and refineries was studied from 1950 to 1969. Comparisons were made with the remaining 2,985 counties in 48 states. In 36 counties with smelters processing copper, lead, or zinc ores, lung cancer mortality was significantly higher both among males ($p < 0.01$) and females ($p < 0.05$). For all 36 counties with these industries the median SMR was 112 for males and 110 for females. Although occupational cancers were included in the analyses and, therefore, contributed to some of the excess risk, the number of workers in the smelter industry generally comprised a small fraction of the total population (less than 1 to 3 percent); thus, it was unlikely that occupational exposures alone accounted for the observed excess mortality in males or the increased risk for females. Although this study is suggestive of a lung cancer effect in populations surrounding smelters, it is unknown if the lung cancer cases were even exposed to arsenic. Thus, the results, although suggestive, are inconclusive.

In the Baltimore, Maryland area, Matanoski et al. (1976, 1981) studied cancer mortality in areas near the earlier mentioned pesticide facility. They found an excess of all cancers and respiratory cancers among males in the area nearest to the factory but not among females. Soil arsenic levels generally corresponded to lung cancer and all cancer incidences, with the highest average of arsenic in the soil (63 ppm) reported in the area with the greatest cancer risk. The authors were unable to account for the differences noted between males and females, but suggested that smoking may have contributed to these differences. Other environmental factors and/or occupational exposure may have also influenced cancer mortality excess. Further environmental sampling of arsenic and conducting of community surveys were recommended to address these unknown factors.

Pershagen et al. (1977) studied cancer deaths in the area surrounding the Rönnskär smelter in Sweden. From 1961 to 1975 there was a significant excess of respiratory cancers in the male population (SMR = 250) compared to residents in an area without known emissions of arsenic but in which the same age distribution and occupational profiles applied. When the occupationally exposed cases were excluded, significant increases in respiratory cancers were no longer detected (SMR 173); however, the male population still showed a tendency to excess lung cancers. No similar occupational group was excluded from the comparison population, however. There was no tendency to an increase in lung cancer among women.

7.1.2.2 Cancer of the Skin and Precancerous Skin Lesions--An elevation in the proportionate mortality of skin cancer was reported by Hill and Faning (1948) for factory workers manufacturing sodium arsenite and by Roth (1957, 1958) for German vintners. In addition, an increased incidence of skin cancer has been reported after long-term oral exposure to arsenic.

In Taiwan a large population had long-term exposures to inorganic arsenic in drinking water. Exposure started in 1910-20 when water was obtained from deep wells, 100-200 m. below the surface. Already in the 1920s, vascular changes began to appear, and in the 1950s, the first epidemiological studies were conducted. The arsenic content of the water varied from 0.01 to 1.82 mg/l (Ch'i and Blackwell, 1968; Astrup, 1968; Tseng et al., 1968; Tseng, 1977), generally being 0.4 - 0.6 mg/l, whereas water from shallow wells or other surface waters generally contained from near zero to 0.15 mg As/l.

Tseng et al. (1968) and Tseng (1977) have reported the results from a large-scale epidemiologic survey of arsenic-related diseases in an area with high arsenic concentrations in drinking water. The population at risk was 103,514 persons. Thirty-seven villages with a population of 40,421 were surveyed house-to-house. Examinations were made with special attention to pigmentation, hyperkeratosis, and cancer of the skin. Four hundred twenty-eight cases of arsenical skin cancer were found, resulting in a rate of 10.6/1000. No cases were under 20 years of age. The prevalence rate increased markedly with age except for females >70. Over 10 percent of the people >59 were affected by skin cancer. The overall male/female ratio was 2.9:1, with males having a higher rate in all age groups >29.

The villages were divided into 4 exposure levels: <0.3, 0.3-0.6, $\geq$0.6, and undetermined, based on their water arsenic content. There was a clear cut ascending gradient of prevalence from low to high in each of 3 age groups (Table 7-16).

Hyperpigmentation (melanosis) was found in 18.4 percent of the total population: 19.2 percent for males and 17.6 percent for females. Usually the prevalence was higher for males than females. The rates increased steadily with age for males and did likewise for females until a peak was reached at 50-59, followed by a gradual decline.

TABLE 7-16. PREVALENCE OF SKIN CANCER (per 1000) BY AGE AND ARSENIC EXPOSURE (ppm)

Arsenic content of drinking water (ppm)	Age 20-39	40-59	>60
<.3	1.3	4.9	27.1
0.3 - 0.6	2.2	32.6	106.2
>0.6	11.5	72.0	192.0

Source: Adapted from Tseng et al. (1968).

The overall prevalence rate for keratosis was 7.1 percent - 7.5 percent for males and 6.8 percent for females. Males had higher rates in the greater than-49-year group. The prevalence increased for both males and females up to age 70 and then declined.

As was the case for skin cancer, the prevalence rates for hyperpigmentation and keratosis suggested that positive correlations existed between these conditions and the arsenic content of the water in the artesian wells; the greater the arsenic content, the higher the prevalence.

In the total survey of 40,421 people, 7418 cases of hyperpigmentation, 2868 of keratosis, 428 of skin cancer, and 360 of Blackfoot disease (see Section 5.2.2) were found. Many of these occurred in combination in the same individual.

The data were examined by comparing expected (based on overall rates) and observed rates for various combinations of the 4 end points. The obtained ratios indicated quite strongly that a common underlying cause existed for the 4 conditions, presumably chronic arsenicism.

A control population of 7500 persons from nonendemic areas was examined in the same way as the arsenic-exposed persons. Four thousand, nine hundred

and seventy-eight people lived on Matsu Island; its water supply was from shallow wells and no arsenic was detectable by the analytic methods used in the main series. The remaining portion of control population members came from 5 villages on Taiwan whose water source was shallow wells with arsenic levels between 0.001-0.017 mg/ℓ (ppm). No cases of melanosis, keratosis, or skin cancer were observed in the entire control population.

Although age at onset of the conditions was difficult to assess, some information on latency was obtained. "We know from the study that the youngest cancer patient was 24, the youngest with hyperpigmentation was 3, and the youngest with keratoses was 4." This meant that hyperpigmentation could occur in patients who were exposed from birth for at least 3 years, keratosis for 4 years, and cancer for 24 years (Tseng et al., 1968).

While the Taiwanese data collected in the late 1960's strongly implicated arsenic as the etiological source of the observed diseases, recent findings have called to question the hypothesis of arsenicism as sole causative source in the induction of cardiovascular effects. The discovery by Lu et al. (1977b, 1978) of fluorescent compounds identified as alkaloids--either lysergic acid, dihydrolysergic acid or a derivative of ergotamine tartfate--has opened the possibility that other toxic mechanisms may have been involved. Ergotamine-like compounds in combination with high alkalinity, characteristic of these waters, have been shown to cause gangrene (Lu et al., 1977a,b; 1978). Whether these compounds have a confounding effect on skin cancer is presently unknown.

In addition, recent analyses by Irgolic (1982) on a limited number of samples have shown the water samples to contain predominantly pentavalent arsenic and no organic arsenicals. Samples taken from two wells in the Yenshei Province of Taiwan were collected in plastic cubitainers. Two samples each of unpreserved water and water preserved either by addition of 0.1 weight percent

of ascorbic acid or by acidification of 0.1 M HNO_3 were sent to the U.S. for analysis a few days after collection. Treatment of samples by HNO_3 or ascorbic acid was done immediately upon collection (Irgolic, 1983; personal communication). Samples were analyzed during a two-week period after arrival in the U.S., the total time lapse between collection and analyses ranging from one to three weeks. The results of the analyses can be seen in Table 7-17. Additional water samples collected from other parts of Taiwan also contained pentavalent arsenic. However, these samples were less reliable in that the collection period was unknown, and, upon arrival in the U.S., these samples had a yellowish hue with some flocculated matter present (Irgolic, 1982).

Several questions still remain to be answered in regard to water-usage patterns of the Taiwanese. For instance, it is not clear how quickly the water drawn from the wells was consumed; nor is it clear how much of the water was consumed in tea or other beverages where cooking preparations, such as boiling, would have altered the chemical form of the arsenic. These questions need to be answered in light of the possible effect these answers might have on interpreting the observed skin cancer incidence.

Ch'i and Blackwell (1968) conducted a case-control study in the area of Taiwan studied by Tseng et al. The authors compared a variety of factors between 353 cases of Blackfoot disease and 353 controls matched for sex and age. Socioeconomic status, occupation, cigarette smoking, diet, and consumption of deep well water which was arsenic-contaminated were the factors compared. Two factors were found to be significantly different between the cases and controls. Significantly ($P < 0.01$) more cases than controls were found to consume deep well water and to have a lower socioeconomic status. Though the author concluded that the primary contributing cause of Blackfoot disease was consumption of deep well water, the socioeconomic differences cannot be completely discounted.

TABLE 7-17. RESULTS OF TOTAL ARSENIC ANALYSES AND ARSENITE AND ARSENATE DETERMINATIONS IN THE YENSHEI WATER SAMPLES*

Other studies have also explored the relationship of arsenic to skin cancer and various skin lesions. Similar chronic effects as seen in Taiwan have been reported in other countries.

In Antofagasta, Chile, a new water supply was put into service in 1958. In the 1960s, physicians began noticing dermatological manifestations and even deaths, especially among children. In an investigation of skin pigmentation in 27,088 school children from the province of Antofagasta, an overall incidence of 12 percent was reported (Borgono and Greiber, 1972). It was discovered that the drinking water contained 0.8 mg As/l. Borgono and Greiber compared 180 inhabitants of Antofagasta with a community without exposure to arsenic via drinking water. Abnormal skin pigmentation was reported to be present in 80 percent and hyperkeratosis in 36 percent of the Antofagasta inhabitants, whereas none was found in the control group ($p \leq 0.05$).

In 1970, a water treatment plant was installed and there was a considerable drop in arsenic. According to Borgono et al. (1977), there were no skin lesions in children born since the water treatment began. However, it should be noted that in this more recent study the sample size of children born since the water treatment plant began was small (306) and no comparison population was studied. Therefore, any conclusions associating the lack of dermatological manifestations with the decrease in arsenic must take into account the small sample size. In regard to skin cancer, the follow-up may not have been long enough to detect a difference.

In addition to the work of Borgono and co-workers, Zaldivar and Guillier published a series of papers on the Antofagasta situation (Zaldivar, 1974; Zaldivar, 1977; Zaldivar and Guillier, 1977). The first of these (Zaldivar, 1974) describes a study on a total of 457 patients (208 males and 249 females) bearing cutaneous lesions (leukoderma, melanoderma, hyperkeratosis, and squamous cell carcinoma). The cases were collected both by the author and the

local hospital during the period 1968 to 1971. Children 0 to 15 years of age accounted for 69.2 percent of the male cases and 77.5 percent of the female cases. The average incidence/100,000 for cases with cutaneous lesions in 1968 to 1969 were 145.5 and 168.0 for males and females, respectively. By 1971 the incidence rates had dropped to 9.1 and 10.0 for males and females, respectively. The decline in morbidity was so rapid that a conclusion that arsenic was the cause of the skin lesions would have to be considered suspect.

The existence of arsenical waters in an eastern area of the province of Cordoba, Argentina, has been known for many decades (Arguello et al., 1938; Bergoglio, 1964). Effects noted on the population from this area include hyperpigmentation, keratosis, and skin and respiratory cancer. A large area of the province, mainly in the east and somewhat to the south, is the focal point for chronic endemic regional arsenical intoxication (CERAI) (Arguello et al., 1938). This CERAI is due to the ingestion of well water coming from the uppermost sheet of underground water--the principal source of arsenic--as well as to the ingestion of arsenic from the wells, which varies among wells throughout the region. The concentration also varies with rainfall. Vanadium is also elevated in areas with high arsenic content. A later report (Bergoglio, 1964) indicates that progress had been made in improving the hygienic condition of the drinking water.

Arguello et al. (1938) summarized the early history of investigations (1913 to mid-1938) into the health outcomes associated with the ingestion of arsenic-contaminated water. They also reported the results of an investigation of a large series of epitheliomas collected from mid-1932 to September 1938 at the dermatosyphilology clinic of a medical school in the arsenic-contaminated area. The series consisted of 323 cases of epithelioma of which 39 or 12.1 percent were cases with clinical evidence of CERAI.

Patients exhibiting CERAI had characteristic cutaneous lesions, represented by the symmetrical palmo-plantar keratoderma and melanoderma, although the latter symptom was seen less frequently. Foot and hand keratoderma were seen in 100 percent of the CERAI patients. Appearance usually occurred 2 to 3 years after the onset of intoxication. A prodrome of the keratosis is the appearance of an erythema in the same location, and a subjective crawling sensation and local fever. Otherwise, it is a state of dryness which precedes the keratosis.

Arguello et al. (1938) also reported that most patients also had hyperhidrosis and abnormalities of pigmentation. The melanoderma appeared early in the process and was variable among patients. It was described as small dark spots ranging in diameter from 1 to 10 mm. They had a tendency to coalesce and appeared predominantly on the trunk in the areas not exposed to the sun. Atropy was associated with telangiectasia and loss of color, or leukoderma, between the hyperpigmented areas (the "raindrop" appearance cited by Reynolds, 1901).

Geographically, the largest proportion of cases in the clinic came from the areas with the highest incidence of CERAI. Because the authors' data are not population-based, however, it cannot be stated that the incidence of skin cancer is significantly increased in these areas. The authors reported that the hands and feet were the locations of choice for the arsenical epitheliomas (38.5 percent vs 3.9 percent) compared to the nonarsenical epitheliomas. An example of this was seen in the head where 81.6 percent of the nonarsenical epitheliomas occurred versus 15.4 percent for arsenical epitheliomas.

Bergoglio (1964) did a proportionate mortality study of residents of certain departments (counties) in the Province of Cordoba, Argentina, where endemic arsenic levels in the water supply are reported to be very high. The

proportion of cancer deaths was higher in those departments than for the province as a whole (23.84 percent versus 15.3 percent; $P < 0.05$). Of the cancer deaths, respiratory cancer constituted 35 percent and skin cancer 2.3 percent. From the description by the author, it can probably be inferred that these data are not age-adjusted. No comparison is made of the percentage of respiratory and skin cancer deaths in the affected departments with the respective proportion for Cordoba Province.

Morton et al. (1976) investigated the relationship of skin cancer morbidity and the ingestion of arsenic-contaminated drinking water in Lane County, Oregon. The southcentral region of Lane County is underlaid by an arsenic-rich stratum called the Fisher formation, which is known to produce high arsenic levels in waters from wells drilled into the land. An extensive search of the pathology records of medical providers in Lane County, Oregon, was conducted in 1972 for the occurrence of skin cancer during the years 1958 to 1971. Cases were thoroughly screened to eliminate duplications and were then coded to 1970 census tract numbers according to the residential address at the time of diagnosis. Water samples were obtained in all census tracts at selected points in all municipalities and water districts in the county, as well as from single-family water sources. The single-family water sources were neither randomly nor uniformly distributed throughout the county but instead were heavily concentrated in the regions believed to have water arsenic problems. Water samples collected during 1968 to 1974 were compiled into mean concentrations for each census tract and census tract region. The authors stated that it seemed reasonable to assume that the samples were representative of the earlier time periods as well.

The skin cancer data were expressed in four sets of rates because of the availability of 4 sets of population estimates. Overall mean annual incidence

rates for the entire 1958 to 1971 period used mean population estimates based on all four sets of denominators. Census tract regions were devised to simplify analysis and presentation. Table 7-18 presents the water arsenic level obtained. As can be readily seen, the South rural area had a much greater arsenic exposure than any of the other sections of the county. Figure 7-1 contrasts the parts of the county underlaid by the Fisher formation, and subsequent higher arsenic levels, with the parts of the county experiencing higher squamous cell skin cancer. Relatively little concordance is noted. A multiple regression analysis performed by the authors demonstrated essentially no relation between skin cancer and water arsenic. It should be noted that water arsenic levels in this study varied from 0 to 2150 ppb. The authors point out that the Lane County water arsenic levels were much lower than those reported for Taiwan and Antofagasta. In particular, only 5 percent of the Lane County samples contained 100 or more ppb of arsenic in contrast to 48 percent of the samples in that range in the Taiwan data.

Similar findings were reported by Southwick et al. (1981) in a study conducted on residents of West Millard County, Utah. As an area in which naturally occurring arsenic in public drinking water had been reported, West Millard provided an "excellent opportunity to study the effects of arsenic exposure on a homogeneous, stable population with a predominantly 'Mormon lifestyle'" (Southwick et al., 1981). The exposed communities of Hinckley and Deseret had average arsenic concentrations of 0.18 mg/l and 0.27 mg/l, respectively (based upon monthly water samples taken between May 1976 to May 1977). The control community of Delta had average arsenic concentrations of 0.02 mg/l. All drinking water in the study communities came from wells and the predominant species of arsenic was reported as the pentavalent form (85 percent).

All study participants from the exposed communities were required to be five years of age or older and to have been residents of Hinckley or Deseret for at least the previous five years. Control participants were selected at random from age and sex categories matched to the exposed participants. Control participants were required to have lived their entire lives either in Delta or communities where arsenic in drinking water did not exceed the national standard of 0.05 mg/l.

Physical examinations were conducted to detect signs and symptoms associated with chronic arsenic poisoning. A total of 250 people participated in these examinations (145 exposed, 105 control); not all of these participated in each part of the examination, however. No explanation was provided by the authors as to the differences in participation rate for different parts of the examination. Urine and hair samples were collected from 94 and 74 percent of the participants, respectively. Dermatological examinations were conducted on 249 individuals. Neurological and hematological examinations were also conducted and are discussed in Sections 5.2.1 and 5.2.4, respectively. In addition, the incidence of cancer and vascular diseases in the study population was compared to other counties in the state of Utah.

The study results showed a clear relationship between the amount of arsenic consumed in drinking water and the amount measured in hair and urine. Differences between exposed and control populations were statistically significant.

Of the 249 participants examined for dermatological signs of arsenic toxicity (palmar and plantar keratosis and hyperkeratosis, tumors, diffuse pigmentation, arterial insufficiency), only 12 showed such signs and no participant had more than one sign. The 12 individuals were not clustered among the more heavily exposed, and when the dermatological signs were regressed

against annual arsenic dose and the log of the dose, no significant associations were found.

Age-adjusted cancer incidence rates showed Hinckley to have a somewhat lower cancer incidence than Delta. Cancer death rates, 1956 to 1976, showed Hinckley to have the highest rate (138 per 100,000) when compared to 42 other Utah communities. Table 7-19 shows age-specific death rates for Utah and three Millard County communities. (Fillmore is the County seat; comparisons to Deseret were not made due to the community's small population). Between 1956 and 1976, 14 cancer deaths were reported for Hinckley. All of these deaths occurred in individuals 45 years or older and the cancers were types most frequently reported for Utah: lung, breast, large intestine, prostate, stomach, leukemia, kidney, uterus, bone and connective tissue. Hinckley had generally lower death rates for cardiac and vascular diseases than did the control community of Delta. The authors noted that no unusual death patterns likely to be associated with arsenic exposure were seen in Hinckley.

Certain weaknesses exist with this study, most notably, that of a small study population from which to derive meaningful statistical analyses. Furthermore, children and adults were not treated separately. In regard to sample size, the authors felt that the small sample size was somewhat compensated by the homogeneity and stability of the predominantly nonsmoking population. Data on food consumption were also missing which might have influenced urinary arsenic levels. This, in turn, may have resulted in overstating the strength of the dose-response relationship for urinary arsenic and arsenic in drinking water. It should also be noted that some participants were reported to have an average daily water consumption greater than 8ℓ, which seems very high, even

taking into account the hot summers. In reporting on the lack of arsenic-related effects in this study population compared to others (Tseng et al., 1968; Borgono and Greiber, 1972; Borgono et al., 1977; Zaldivar, 1977; Zaldivar and Guiller, 1977), the authors did note that populations in Taiwan and Antofagasta were exposed to considerably higher concentrations of arsenic in their drinking water.

Interestingly, the importance attached to the fact that no adverse effects were seen in this group of individuals exposed to drinking water arsenic levels four times that allowed by the Interim Primary Drinking Water Regulations (0.05 mg As/l) is somewhat compromised by the very characteristics of the population that make it useful for epidemiological study. The fact that this study population is so homogeneous and stable and, therefore, lends itself to a relatively well controlled statistical analysis, also makes it less useful in terms of being representative of the overall population of the U.S. For this reason, any generalizations that might be drawn from this study population are subject to limitations.

In addition to exposures via drinking water, food exposures and therapeutic exposures have also caused skin lesions and cancers. Hyperpigmentation and depigmentation of the skin were found to be common among the survivors of the Morinaga milk poisoning in 1955. A follow-up study conducted on the exposed children when they were 17-20 years of age showed the prevalence of lesions to be 15 percent (Yamashita et al., 1972). It is not known if any skin cancers have developed.

Hutchinson (1888) first reported on a possible association of skin cancer with the use of arsenical medicines. Prior to that, the association between these arsenical agents and keratotic lesions had been recognized. In his classic paper, Hutchinson reported on 6 patients with case histories who

exhibited the keratotic lesions associated with arsenical poisoning. He felt that the clinical series supported two principal conclusions:

1. Prolonged internal use of arsenic may seriously affect the nutrition of the skin and that use may produce warty or corn-like indurations.

2. Continued use of arsenic may result in a tendency for these "arsenic corns" to grow downward and pass into epithelial cancer.

Neubauer (1947) later compiled a series of reports on 143 cases of medicinal arsenical epitheliomas. He excluded five categories of cases reported in the literature to keep the series consistent with regard to diagnosis of case and history of arsenical use. Seventy-one percent of the patients being treated with arsenical medicine were patients suffering from skin diseases, especially psoriasis (54 percent). In contrast, only a small percentage of the cases reported came from patients treated with arsenic for various internal disorders. In nearly all cases the drugs used were inorganic and almost all were trivalent. The most commonly used arsenical was potassium arsenite. No externally applied arsenic-related skin cancer case was reported in the series.

The elapsed time from the beginning of administration of the arsenical drug to the beginning of the epitheliomatous growth was variable, but averaged 18 years regardless of the type of lesion. In cases with keratosis, the latent period to the onset of keratosis was about half the latent period to the onset of the epithelioma, i.e., about 9 years. Thirty-three percent of the patients were 40 or younger. Of the 143 patients, 13 had or developed miscellaneous cancers at other sites, but such cases were not reported systematically.

Fierz (1965) reported a follow-up study of patients treated with arsenic by a private practitioner. An accurate assessment of the total arsenic intake

in terms of the amount of Fowler's Solution administered was available to the investigator from patient records. The follow-up examination was conducted under the auspices of a local polyclinic. Fourteen hundred fifty patients were identified as having received arsenic treatment, and invitations were mailed for them to come for a free follow-up medical examination. During the period March 1963 to April 1964, 262 patients presented themselves for examination. Two hundred eighty patients were not located while 100 patients actively refused to participate. Only patients under 65 years of age were invited to participate in the study. The author admits that the patients reporting for examination were not a representative sample. In fact, he categorizes them into three groups which range the spectrum of likely biases. There were patients satisfied with the results of the arsenic treatment and wishing to express thanks, patients in whom disturbing side effects were occurring, and finally patients who were still suffering from the initial disease and who were eager to get a consultation.

Arsenic treatment was prescribed for individuals suffering primarily from three main skin diseases: psoriasis (64 patients), neurodermatitis (62), and chronic eczema (72). In addition, treatment was also prescribed for 64 patients suffering from assorted skin diseases other than those listed above.

Fierz noted that the arsenic treatment showed good success. Of the 64 cases of psoriasis, 55 reported a favorable effect while taking the drops. Forty-eight of 62 patients with neurodermatitis reported a favorable effect. This effectiveness was the cause for the patients' reliance on the drug.

Upon examination, 106 of 262 patients (40.4 percent) reported hyperkeratoses, although frequently a detailed examination was necessary to find the changes. Hyperkeratoses were round, superficially verrucose papules, 1 to 3 mm in diameter. The number and the exact presentation of the hyperkeratoses varied from case to case.

In the series, 21 cases of skin cancer were found comprising 8 percent of the total subjects. As was in the case of hyperkeratosis, some variability was observed in the expression of the skin cancers. Multiple basal cell carcinoma was the most frequent histologic type observed, occurring in 48 percent of the cancer patients. The basal cell carcinomas appeared morphologically as polycyclic, sharply bounded erythemas with slight infiltration. In 13 of the 21 cancer cases, multiple carcinomas were observed, a much higher proportion than had been observed with other causes of skin cancer. Of the 21 patients with carcinomas, 16 showed distinctly developed arsenic warts on the palms and soles simultaneously with the skin tumors.

Both hyperkeratosis and skin cancer were found to vary with increasing arsenic intake. Above 400 ml of Fowler's solution, more than 50 percent of the patients studied showed hyperkeratosis. As the dose increased there was a corresponding increase in the simultaneous occurrence of hyperkeratosis of the palms and soles. Only 2/15 cases of hyperkeratosis with intakes of up to 250 ml had a simultaneous presentation, while 16/27 had a simultaneous presentation with intake of 250 to 500 ml.

As with the hyperkeratosis, skin cancer increased with increasing arsenic doses. Below 500 ml only basal cell carcinomas were found; spindle cell carcinomas were only found above that dose. The latency period for hyperkeratosis was at a minimum 2.5 years; skin cancer, however, had a minimum latency period of 6 years with a mean latency period of 14 years.

Cuzick et al. (1982) conducted a mortality analysis of a cohort of 478 patients given Fowler's solution to determine if persons taking the solution were at an increased risk of internal malignancies. The cohort consisted of 213 males (45 percent) and 265 females (55 percent) who took Fowler's solution for various lenghts of time ranging from 2 weeks to 12 years (mean duration,

8.92 months) during the period of 1945-1969. Follow-up was until January 1, 1980; the mean follow-up time for the entire cohort was 20.3 years. The median cumulative dose of arsenic was reported as 448 mg, with most patients consuming arsenic at a rate of about 250 mg/month.

Within the defined risk period, 139 patients died, 265 patients were known to be alive and at risk, 29 had passed 85 years of age, 19 had emigrated, and 26 could not be traced. Because of the unreliability of the expected values in the open-ended group beyond 85 years of age, deaths and person-years at risk after age 85 were ignored. Persons who emigrated were censored as of the date of emigration.

A subset of 142 of the cohort were physically examined during 1969-70, and the presence of arsenical keratoses, hyperpigmentation, and skin cancer was recorded. No signs of internal malignancy were clinically apparent at the time of examination. This subset was chosen because the individuals were known to be alive and were able to be traced.

The results showed that risk ratios were similar for both males and females. No signs of internal malignancy were clinically apparent in the patients given physical examinations, and mortality was not found to be significantly increased for any internal malignancies in the cohort, although it was somewhat elevated for death from bladder cancer (observed = 3, expected = 1.19, $P = 0.12$). The ratio of observed-to-expected deaths from all neoplasms, from cancer of the digestive organs, from cancer of the respiratory organs, and from all causes was analyzed by cumulative dose level. No trend by cumulative dose level was found; however, the risk ratios were low for deaths from all neoplasms, digestive cancers, and respiratory cancers in the lowest dose group, with the risks for deaths from all neoplasms being significantly ($p < 0.05$) lower than expected. A significant positive trend in the ratio of

observed-to-expected mortality for all neoplasms was found for dose in the period 5-9 years from first exposure, but this trend was not found in other time intervals since first exposure.

Of the subset of 142 patients examined for skin manifestation of arsenicism, their overall mortality was consistent with the remainder of the cohort. Within this group, 45 percent had keratosis, 14 percent had hyperpigmentation, and 11 percent were found to have skin cancer. The authors did not indicate what the expected proportions of patients with these signs would be. Some patients showed 2 or all 3 signs of arsenicism, and 49 percent showed at least one of the signs. The appearance of signs was dose- and age-related. Patients with signs had higher median doses (672 mg) than those without any signs (448 mg), and this was significant ($P < 0.001$) by the Wilcoxon rank-sum test. Forty percent of patients with signs had cumulative doses above 1000 mg, whereas only 22 percent of the patients without arsenical signs had cumulative doses above 1000 mg. On the average, patients with signs were 7 years older and had received their first exposure 6 calendar years earlier than those without signs. Within the group with exposures > 1000 mg, those with signs were, again, an average of 7 years older, and they had their first exposure 3 years earlier. It is interesting to note that all seven of the subsequent deaths from internal malignancy in this subgroup had been identified as showing signs of arsenicism. No deaths from cancer occurred in the group without physical signs.

In summary, this study provided little evidence that ingestion of arsenic is related to a risk of mortality from internal malignancies. Non-fatal skin cancer was found, however, to be related as a function of dose to ingestion of Fowler's solution. The authors indicated that perhaps persons who demonstrate signs of arsenicism following arsenic exposure retain arsenic longer than those

who do not show signs, which may suggest that persons who demonstrate signs of arsenicism are at a greater risk of internal malignancies. This was suggested by the fact that all of the deaths from internal malignancies in the subset of individuals that was examined for signs of arsenicism occurred in individuals who demonstrated such signs.

Knoth (1966) also reported on two patients treated with arsenical medicinals and who developed skin cancer. Roth (1958) reported that of 47 autopsy cases of vintners with chronic arsenic intoxication, 13 had skin tumors.

Gilbert et al. (1983) conducted a study on wood treaters in Hawaii who were occupationally exposed to arsenic (see Section 7.1.2.1 for complete discussion of study). The authors found no evidence of risk of skin cancer, but inadequacies in the study design and the small sample size limit the ability to draw valid conclusions from the data.

7.1.2.3 Other Cancers--Whereas there are many studies suggesting that there is an association between inhalation exposure and respiratory cancer and oral exposure and skin cancer, respectively, there are no consistent data with regai to cancer in internal organs.

Reymann et al. (1978) have investigated the relationship between the intake of arsenic for medicinal purposes and subsequent internal neoplasms. Study subjects were identified by examining the files of a dermatology clinic in Denmark for the years 1930 to 1939. Two rosters of study subjects were generated: 1) persons treated with arsenic for multiple basal cell carcinoma, Bowen's disease, psoriasis, verruca planus, and lichen planus, and 2) persons with keratoses from the first roster plus 30 other persons identified as having keratoses. The first roster of 413 persons comprised the basic study population; 24 persons were excluded for various reasons, resulting in a final study population of 389 persons. The malignancy histories of both populations

were traced through the years 1943-1974 in the Danish Cancer Registry. For each person a length-of-observation period was determined and an expected number of internal malignant neoplasms was determined using the former data.

In the main study population, 41 cases were observed versus 44.6 cases expected. Therefore, no increased incidence of internal malignancies was noted in the arsenic-treated patients. However, examination of the data by individual skin disease categories showed that women with multiple basal cell carcinoma had a significantly higher incidence of internal cancer. The same trend, although not significant, was observed in female patients exhibiting verruca planus. Next, an analysis was made of a possible dose-response relationship using duration of treatment as the exposure variable. The categories were low, medium and high, based on <1 month, 1-3 month, and >3 month duration of standard dose administration (6-8 mg As_2O_3). No relationship between dose and internal organ cancer was noted for the total population or by sex. In addition, the form of arsenic administered did not seem to affect the incidence of internal cancer, nor was any effect noted due to period of observation. Reymann et al. did not provide a definition of the term "internal cancer." It is presumed that the authors included lung cancer in their definition. If so, the authors did not provide any adjustment for smoking. Regardless, the sample size of 389 persons is probably too small to detect an excess in the incidence of internal cancer, even if lung cancers were excluded.

The keratosis group was not analyzed in the same way. Eight of the 19 men with keratosis died before 1974. Four of these were due to cancer of the internal organs. Expected deaths were 1.9. Similarly, 5 deaths due to cancer of the internal organs were observed in the 34 women with keratosis compared with 3.3 expected. Together there were 9 deaths due to cancer of the internal organs compared to 5.2 expected. Although the figure is almost doubled, it is

still not significant. On the average, the patients with keratosis received higher doses of arsenic than the other patients.

Hemangioendothelioma and reticulosarcoma of the liver has been reported by Roth (1958) to occur among German vintners exposed occupationally to arsenic. The same type of malignancy occurrence has also been reported in isolated cases by other authors (Pershagen and Vahter, 1979). Higgins et al. (1982) reported increased mortality for cirrhosis of the liver and urinary cancer in workers at the Anaconda Montana smelter.

More recently, Falk and coworkers (1981a) described a nationwide (U.S.) review of deaths from hepatic angiosarcoma during the years 1964-1974. Of 168 confirmed cases included for survey, a group of seven cases with a history of prolonged use of Fowler's solution was found. Taken with the data of Roth, chronic arsenic exposure, mainly via ingestion, appears to be associated with this very rare liver cancer.

In a review of four cases of hepatic angiosarcoma, Falk et al. (1981b) determined that one case, that of a child, involved environmental arsenic exposure in a copper-smelting community in Arizona. Since this child had a history of pica, the usual exposure routes were augmented by further arsenic intake.

Roat et al. (1982) reported a case of hepatic angiosarcoma in a subject who, 33 years earlier, had ingested Fowler's solution for the relatively short period of 6 months. The pre-existence of skin cancer in this subject, from age 25, of the type associated with arsenic exposure, was further support of an arsenic association.

Knoth (1966) reported on two patients who had been treated with arsenical medicinals and developed tumors at sites other than the skin or lung. One of the patients was a 61-year old woman who had been treated with an arsenical

REC 5128

medicinal and developed mammary carcinoma. The other case was that of a 53-year old male who had been treated with an arsenical medicinal for cirrhosis vulgaris and developed a reticulosarcoma of the glans penis.

In the studies by Ott et al. (1974), an increased proportionate mortality due to malignant neoplasms of lymphatic and hematopoietic tissues was found. Axelson et al. (1978) found an increased risk of leukemia and myeloma in a case-control study of workers exposed at a smelter.

7.2 ANIMAL STUDIES

While arsenic carcinogenicity in test animals has not been observed in most studies, some recent reports have noted positive results. The literature on experimental inorganic arsenic carcinogenesis, as summarized in Table 7-20 and as reviewed by scientific bodies (NAS, 1977; NIOSH, 1975; IARC, 1973 and 1980) and individuals (Sunderman, 1976; Wildenberg, 1978; Pershagen and Vahter, 1979) supports this conclusion.

In light of the presently recognized anomalous metabolizing of inorganic arsenic by rats, studies which used rats as the experimental subjects should be viewed cautiously. Studies on other animal models have generally resulted in negative findings. A few of these studies are discussed below, but most have been summarized in Table 7-20.

In a study by Baroni et al. (1963), Swiss mice were given either arsenic trioxide dissolved in drinking water (concentration of 100 mg/ℓ) ad libitum for the duration of the 70-week experiment; or, sodium arsenate in a concentration of 15.8 gm/ℓ in a 2.5 percent solution of Tween 60 in water, applied twice weekly for the duration of the experiment. Each compound was tested alone, in combination with skin applications of croton oil (to test for initiating action), and after initiation with a single skin application of 7,12-dimethylbenz(a)anthracene or with administration of urethan by stomach tube

REC 5129

TABLE 7-20. SUMMARY TABLE OF EXPERIMENTAL STUDIES OF ARSENIC CARCINOGENESIS

Route	Species (Strain)	Compound	Vehicle	Results*	Reference	Remarks
Oral	Mice (C57B16)	As_2O_3	Tap water or 12% aqueous ethanol	-	Hueper and Payne, 1962	Shortened life span of treated (aq. ethanol) vs. control.
Oral	Mice (Swiss)	As_2O_3	Drinking water	-	Baroni et al., 1963	
Oral	Mice (Swiss)	$NaAsO_2$	Drinking water	-	Kanisawa and Schroeder, 1967	Shortened life span, low dose.
Oral	Mice (NMRI)	As_2O_3	Drug (Psor-Intern) or Fowler's solution	+(?)	Knoth, 1966	Significance cannot be determined, uncomplete reporting by author.
Oral	Mice (C3H/St, female)	$NaAsO_2$	Drinking water	-	Schrauzer and Ishmael, 1974	
Oral	Rats (not specified)	$Pb_3(AsO_4)_2$ $Ca_3(AsO_4)_2$	Not specified	-	Fairhall and Miller 1941	Poor survival in treated. As reviewed by IARC (Vol. 23, 1980)
Oral	Rats (Bethesda Blacks)	As_2O_3	Tap water or aqueous ethanol (12%)	-	Hueper and Payne, 1962	
Oral	Rats (Osborne-Mendel)	$NaAsO_2$ Na_3AsO_4	Diet	-	Byron et al., 1967	Reduced survival at highest dose.
Oral	Rats (Long Evans)	$NaAsO_2$	Drinking water	-	Kanisawa and Schroeder, 1969	Low dose.
Oral	Rats (Wistar)	$Pb_3(AsO_4)_2$ Na_3AsO_4 $Pb_3(AsO_4)_2$ + NDEA Na_3AsO_4 + NDEA	Diet Diet Diet Diet	- - - -	Kroes et al., 1974	High mortality and 2 tumors (incidence not reported observed in lead arsenate group).

TABLE 7-20. (continued)

Route	Species (Strain)	Compound	Vehicle	Results*	Reference	Remarks
Oral	Dog	$NaAsO_2$ or Na_3AsO_4	Diet	-	Byron et al., 1967	Weight loss, early mortality, short duration of experiment.
Inhalation	Mice (not specified)	$NaAsO_2$	Aqueous aerosol	-	Berteau et al., 1978	Reported in an abstract form, high incidence in controls.
Intratracheal instillation	Rats (Wistar King) male	(1) As_2O_3 (2) Copper ore (3.95% Arsenic) (3) Flue dust	Not specified	- - -	Ishinishi et al., 1977	One tumor observed in treated, not significant.
Intratracheal instillation	Rats (Wistar King) male	As_2O_3	Aqueous solution	-	Ishinishi et al., 1976	One tumor observed in treated, not significant.
Intratracheal instillation	Rats (BDIX)	$Ca_3(AsO_4)_2$	Bordeaux mixture (contains $CuSO_4$ and $Ca(OH)_2$)	+	Ivankovic et al., 1979	Results cannot be attributed to arsenic alone.
Intratracheal instillation	Golden Hamsters (males)	As_2O_3 ± BP	Carbon carrier + dilute H_2SO_4	+	Pershagen et al., 1983	Adenomas significantly greater than controls ($p < 0.01$). Carcinomas in 3 treated animals vs. 0 in controls.
Intratracheal instillation	Golden Hamsters (female)	As_2O_3	Phosphate buffer	+	Ishinishi and Yamamoto, 1983	As_2O_3 was tumorigenic in a dose-response fashion.

TABLE 7-20. (continued)

Route	Species (Strain)	Compound	Vehicle	Results*	Reference	Remarks
Intratracheal instillation	Rats	Ore dust containing As at two levels of content	Not specified	+	Chung and Liu, 1982	Possible confounding effects of other elements present, unknown. No apparent differences in lung cancer with different As levels in dust.
Skin painting (application)	Mice (not specified)	$KAsO_2$ and As_2O_3	Ethanol	-	Leitch and Kennaway, 1922	Neubauer (1947) failed to confirm this observation.
Skin painting (application)	Mice (S)	$KAsO_2$ followed by croton oil in acetone	Methanol	-	Salaman and Roe, 1956	As reviewed by IARC (Vol. 23, 1980).
Skin painting (application)	Mice (Rockland all-purpose)	(1) $KAsO_2$ followed by croton oil in benzene	80% ethanol	-	Boutwell, 1963	As reviewed by IARC (Vol. 23, 1980).
Skin painting (application)	Mice (Rockland all-purpose)	(2) DMBA followed by $KAsO_2$ in 80% ethanol	acetone	Not carcinogenic	Boutwell, 1963	
Skin painting (application)	Mice (Swiss)	(1) Na_3AsO_4	Water containing Tween 60	-	Baroni et al., 1963	
		(2) Na_3AsO_4 followed by croton oil and DMBA	Water containing Tween 60	No promotional activity observed		
Subcutaneous injection	Mice (Swiss) female Progeny	Na_3AsO_4 Na_3AsO_4	Water Water	+ +	Osswald and Goerttler, 1971	

TABLE 7-20. (continued)

Route	Species (Strain)	Compound	Vehicle	Results*	Reference	Remarks
Subcutaneous implant	Rats (random-bred) male albino	$Ca_3(AsO_4)_2$	Paraffin pellets	-	Arkhipov, 1968	As reviewed by IARC (Vol. 23, 1980).
Subcutaneous injection	Rats (random-bred) male albino	$Ca_3(AsO_4)_2$	Sunflower oil	-	Arkhipov, 1968	
Subcutaneous injection (pre-natal + post-natal)	Mice (CFLP)	As_2O_3	Aqueous solution	+	Rudnai and Borzsony, 1981	Histological description of tumors poor.
Intravenous injection	Mice (Swiss) female	Na_3AsO_4	Water	+	Osswald and Goerttler, 1971	
Intramuscullary injection	Rats (Osborne-Mendel)	Arsenic	Metallic	-	Hueper, 1954	
Intramuscullary injection	Rabbits	Arsenic	Metallic	-	Hueper, 1954	
Oral	Mice (Swiss)	As_2O_3 and croton oil, DMBA or urethan	Drinking water	-	Baroni et al., 1963	
Oral	Mice (STS)	Arsanilic acid or $KAsO_2$ followed by DMBA (skin) then croton oil (skin) in benzene	Diet	-	Boutwell, 1963	As reviewed by IARC (Vol. 23, 1980).

(*) + statistically significant excess tumors observed over controls

\- no statistically significant excess tumors of treated vs. control or no tumors observed

(to test for promoting action). All tests failed to show any carcinogenic activity of the two compounds under the given experimental conditions.

Kanisawa and Schroeder (1969) treated Swiss mice with sodium arsenite (equivalent to 5 µg/ml As) in drinking water for the 30-month duration of their study. In the treated animals, the authors noted 6 malignant and 11 combined malignant and benign tumors out of 103 animals versus 15 malignant and 50 combined malignant and benign tumors out of 170 control animals; thus, the results were negative for showing any carcinogenic effect of sodium arsenite in this study.

In a study of Leitch and Kennaway (1922; as reported in IARC, 1980), 100 mice were given skin applications of a solution of potassium arsenite in ethanol containing 1.8 percent arsenic trioxide (later reduced to 0.12 percent due to a high death rate), thrice weekly for 3 months. Of the 33 mice that lived for 3 months, only one developed a metastasizing squamous cell carcinoma.

In certain animal systems, positive carcinogenic responses have been reported, however. For example, Osswald and Goerttler (1971) exposed pregnant Swiss mice to daily parenteral dosing of sodium arsenate (0.5 mg/kg, solution of 0.005 percent arsenate salt) for a total of 20 injections. Part of the offspring groups received 20 injections of the same level subcutaneously at weekly intervals. Leukemia or lymphoma was seen in 46 percent of the mothers (11/24) at the end of 2 years versus none in the controls. Of the treated offspring, 41 percent (17/41) of the males and about half of the females (24/50) developed leukemia versus only 3 of 55 male and female control offspring (approximately 6 percent). IARC (1973) has criticized this study for the absence of exposure of controls to the appropriate vehicle solution.

Knoth (1966) noted a significant frequency of tumors in 30 mice exposed to Fowler's solution orally (one drop/week, 20 weeks, approximately 5.3 mg As

total),including adenocarcinomas of the skin, lung, and lymph nodes. The absence of experimental details makes critical assessment of this study difficult.

Some recent animal studies have employed different exposure conditions than have been employed in the past. Berteau et al. (1978) have exposed a tumor-susceptible strain of female mice to a respirable aerosol of inorganic arsenic (1 percent aqueous solution of sodium meta-arsenite, 20 to 40 minutes daily, 5 days/week, 55 weeks total). The 30 exposed mice showed neither gross nor histological evidence of neoplasia.

In a two-part study, Ishinishi et al. (1977) examined the carcinogenic and co-carcinogenic effects of various arsenic compounds on male Wistar-King rats. In the first part of the study, arsenic trioxide, an arsenic-containing copper ore (containing 3.95 percent arsenic) or metal refinery flue dust (containing 10.5 percent arsenic) were administered to 51 rats via 15 weekly intratracheal instillations. The rats were observed over their lifespan. Of the 25 surviving rats, one adenocarcinoma was seen in the group receiving flue dust. One lung metastasis from osteosarcoma of the femur and one adenoma was reported in the group exposed to the copper ore. No malignant tumors were reported in the group receiving arsenic trioxide; however, one adenoma was reported for this group. All groups displayed squamous cell metaplasia in the airway and osteometaplasia in the alveolus of the lung.

In the second part of the study, 87 rats were instilled with each of the above compounds suspended in a saline solution containing benzo[a]pyrene (B[a]P) or with B[a]P, alone. Control rats (23) were instilled with the saline solution. Of the 34 surviving exposed rats, one adenocarcinoma was seen in the group receiving B[a]P plus copper ore. All exposed groups had squamous cell carcinomas of the lung. Of particular interest to the authors, was the noted co-carcinogenic effect of arsenic trioxide with B[a]P; rats in

this group exhibited a 43 percent incidence rate (3/7) for squamous cell carcinomas. This compared with a 14 percent (1/7) incidence rate in animals given B[a]P, alone. No benign or malignant tumors were seen in the 7 surviving control rats. Again, squamous cell metaplasia or osteometaplasia were seen in all groups.

The results indicated a positive interaction between arsenic trioxide and B[a]P; however, the authors noted that the numbers of surviving animals were too small to permit drawing any firm conclusions from the study.

In another study, Ishinishi et al. (1980) gave 30 male adult Wistar rats intratracheal instillations of arsenic trioxide in suspension for 15 weeks. Of the 19 rats that survived, only one malignant squamous cell carcinoma was observed over lifetime. No tumors were found in the controls.

Ivankovic and co-workers (1979) exposed rats, via intratracheal instillation, to a pesticide mixture corresponding to that used in the past for vineyard treatment and consisting of a mixture of copper (II) sulfate, calcium hydroxide and calcium arsenate. Of 25 rats exposed to approximately 0.07 mg arsenic, 10 died from lung necrosis or pneumonia. In the survivors, 9 animals (60 percent) showed multi-focal bronchogenic adenocarcinomas and bronchiolar/alveolar cell carcinomas.

This study appears to offer experimental evidence that the vineyard pesticide mixture, employed as such, could have been carcinogenic to vine dressers working with the material. One difficulty with this study is an ambiguity regarding its full significance for the general issue of arsenic-inducing carcinogenic effects by itself. Clearly, the high mortality rate, 40 percent, and the known toxicity of Bordeau mixture (copper sulfate plus calcium hydroxide) to animals (Pimentel and Marques, 1969) and man (Villar, 1974, Pimentel and Marques, 1969) suggest carcinogenesis; however, it is impossible

to clearly ascribe such activity to arsenic alone given the presence of other compounds within the mixture. In their studies, Ivankovic et al. (1979) did not include animal groups exposed to calcium arsenate alone or to Bordeau mixture alone.

Pershagen et al. (1983, in press) have studied the pulmonary carcinogenicity of arsenic trioxide alone and in combination with benzo(a)pyrene in male golden hamsters given 15 weekly intratracheal instillations of 3 mg As/kg and/or 6 mg/kg B[a]P. In this study, a carbon dust carrier with dilute sulfuric acid was employed to enhance retention of arsenic. Carcinomas of larynx, trachea, bronchi and lungs were found in 3 animals given just arsenic versus a zero response in controls. The incidence of adenomas, papillomas and adenomatoid lesions was higher in arsenic versus control groups ($p < 0.01$). While the carcinomas in the arsenic group did not reach statistical significance, the significantly higher incidence of the adenomas, papillomas, and adenomatoid lesions support the authors' conclusion that the carcinomas were not a chance finding. The use of the carrier to enhance lung retention of arsenic appears to be the key to the results in this study. By itself, the oxide of arsenic is rather rapidly cleared from the lung (see below).

Rudnai and Borzsony (1981) reported that a combination of pre- and postnatal exposure of CFLP mice to injected arsenic trioxide (1.2 µg As/g, days 15-18 of gestation; 5 µg As/animal for 3 days post-birth) resulted in a 63 percent lung tumor incidence at 1 year of age versus approximately 18 percent in controls. In this study, a detailed histological description of the tumors was not given, but it can be assumed that both adenomas and adenocarcinomas were observed.

Chung and Liu (1982) reported that the repeated intratracheal instillation of ore dust containing arsenic in rats resulted in a lung cancer incidence

rate of approxiamtely 15 percent (6/41) over a period of 3 years, while controls (N=18) showed no lung tumors. There was extensive metastasis in one animal. In this study, two compositions of metal content in ores were used, with the arsenic varying by 8-fold. The lung cancer rate for the two forms of ore dust were comparable, despite the 8-fold difference in arsenic, i.e., there was no simple dose response. On the other hand, the ores contained variable amounts of iron and lead, which may have affected both the dose response and, possibly, the actual incidence of the lung cancers.

Ishinishi and Yamamoto (1983) exposed female golden hamsters to arsenic trioxide by intratracheal instillation of a suspension in phosphate buffer, 15 times weekly, for 4 months, at a total dose of 5.3 mg As. A second group was given a total dose of 3.8 mg As. All animals were followed over their entire life span. The incidence of lung tumors (adenomas) for the combined exposure groups was approximately 17 percent versus no tumors in surviving controls. While the sample size was small, there was the suggestion of a dose response across the two exposure levels (3/10 for the higher dose; 1/10 for the lower dose). These data suggest that arsenic trioxide is tumorigenic in the golden hamster and may be carcinogenic.

Recently, both Inamasu et al. (1982) and Pershagen et al. (1982) have studied the effects of intratracheal instillation of calcium arsenate (see Section 4.1.1 for complete discussion of studies). Inamasu et al. gave single intratracheal instillations of arsenic trioxide or calcium arsenate to male Wistar rats. Pershagen et al. instilled male Syrian golden hamsters with four weekly suspensions of arsenic trioxide, arsenic trisulfide and calcium arsenate. The results of both studies showed that arsenic trioxide was rapidly cleared from the lungs, whereas calcium arsenate was slowly eliminated. The differences in clearance appeared to be related to solubility, with the less soluble calcium arsenate exhibiting the slowest clearance.

These recent findings might help to explain the differences noted above in the earlier studies of Ishinishi et al. (1977; 1980) and Ivankovic et al. (1979). In regard to the Ivankovic study, it may be that the calcium arsenate, of itself, contributed to the high mortality rate observed in the exposed rats.

Schrauzer and co-workers (Schrauzer and Ishmael, 1974; Schrauzer et al., 1977; Schrauzer et al., 1978) have reported experimental results using oral arsenic and the tumorigenic effect of the agent on spontaneous mammary adenocarcinomas in an inbred strain of mice (C_3H/St Mice). These workers noted that while arsenic retards the overall incidence of tumor formation (10 or 80 ppm As), it stimulates the growth of tumors that otherwise occur. When these animals were exposed to only 2 ppm As (arsenite) in drinking water, compared to levels of 10 or 80 ppm, there was no effect on frequency of tumors, although the same enhanced tumor growth was seen as before with levels of 10 or 80 ppm As (Schrauzer et al., 1978). Furthermore, a higher incidence of multiple tumors of the mammary gland was observed, as was the abolishing of the anticarcinogenic effect of selenium in this system when both elements were given together.

In support of the positive responses noted in the above animal studies, Dipaolo and Casto (1979) reported the transformation of cultured Syrian hamster embryo cells by direct exposure to sodium arsenate (NA_2HAsO_4). In their assay, 300 cells from secondary cultures of Syrian hamster embryo cells (HEC) were plated in complete medium with 20 percent serum in 50-mm plastic Petri dishes along with 6×10^4 HEC cells which had been irradiated as confluent monolayer cultures. Sodium arsenate at concentrations of 0 µg/ml (control), 2.5 µg/ml and 5.0 µg/ml in complete medium (with a final concentration of acetone less than 0.02 percent) were added 24 hours later. Dishes were fixed and stained nine days after seeding. Colonies were scored blind by two observers.

For the two sodium arsenate concentrations, the authors reported that the number of transformations were 1.16 and 2.08/dish, respectively, or 1.74 and 4.13 percent, respectively, on the basis of transformed colonies relative to total colonies scored. The authors also reported that typical colonies scored as transformed after direct treatment with a metal carcinogen were identical to those obtained with other chemical carcinogens. In addition, the authors claimed (data not shown) that when 2.5 µg benz(a)pyrene per ml of medium were used, the transformation frequency, on a colony basis, was 4 to 6 percent.

7.3 QUANTITATIVE CARCINOGEN RISK ESTIMATES

7.3.1 Introduction

This quantitative section deals with the unit risk for arsenic in air and water and the potency of arsenic relative to other carcinogens that the Carcinogen Assessment Group (CAG) of the U.S. Environmental Protection Agency has evaluated. The unit risk estimate for an air pollutant is defined as the lifetime cancer risk occurring in a population in which all individuals are exposed continuously from birth throughout their lifetimes to a concentration of 1 $\mu g/m^3$ of the agent in the air they breathe. The unit risk estimate for water is defined similarly, but with a water concentration of 1 µg/ℓ. Unit risk estimates are used for two purposes: (1) to compare several agents with each other in terms of carcinogenic potency, and (2) to give a crude indication of the human health risks that might be associated with exposure to these agents, if the actual exposures are known.

The data used for quantitative estimates can be of two types: (1) lifetime animal studies, and (2) human studies where cancer risk has been associated with exposure to the agent. It is assumed, unless evidence exists to the contrary, that if a carcinogenic response occurs at the dose levels used in a study, then responses at all lower doses will occur with an incidence that can be determined by an appropriate extrapolation model.

There is no solid scientific basis for any mathematical extrapolation model that relates carcinogen exposure to cancer risks at the extremely low concentrations which must be dealt with in evaluating environmental hazards. For practical reasons, such low levels of risk cannot be measured directly either by animal experiments or by epidemiologic studies. It is necessary, therefore, to depend on current knowledge of the mechanisms of carcinogenesis for guidance as to the correct risk model to use.

At the present time, the dominant view is that most cancer-causing agents also cause irreversible damage to DNA--a position supported by the fact that a large proportion of agents that cause cancer are also mutagenic. There is reason to expect that the quantal type of biological response, which is characteristic of mutagenesis, is associated with a linear non-threshold dose-response relationship. Indeed, there is substantial evidence from mutagenesis studies with both ionizing radiation and a wide variety of chemicals that this type of dose-response model is the appropriate one to use in estimating cancer risks from environmental exposures. This is particularly true at the lower end of the dose-response curve. At higher doses, there can be an upward curvature, probably reflecting the effects of multistage processes on the mutagenic response. The linear non-threshold dose-response relationship is also consistent with the relatively few epidemiologic studies of cancer responses to specific agents that contain enough information to make the evaluation possible (e.g., radiation-induced leukemia, breast and thyroid cancer, skin cancer induced by arsenic in drinking water, liver cancer induced by aflatoxins in the diet). There is also some evidence from animal experiments that is consistent with the linear non-threshold model (e.g., the initiation stage of the two-stage carcinogenesis model in rat liver and mouse skin).

Because of these factors, the linear non-threshold model is considered to be a viable possibility for the true dose-response relationship and, unless

direct evidence to the contrary is presented, it is used as the primary basis for risk extrapolation at low levels of exposure.

The quantitative aspect of carcinogen risk assessment is included here because it may be of use in setting regulatory priorities, evaluating the adequacy of technology-based controls, and other aspects of the regulatory decision-making process. However, the imprecision of presently available technology for estimating cancer risks to humans at low levels of exposure should be recognized. At best, the linear extrapolation model used here provides a rough but plausible estimate of the upper limit of risk--that is, with this model it is not likely that the true risk would be much more than the estimated risk, but it could be considerably lower. The risk estimates presented below should not be regarded, therefore, as accurate representations of true cancer risks even when the exposures involved are accurately defined. The estimates presented may, however, be factored into regulatory decisions to the extent that the concept of upper-risk limits is found to be useful.

7.3.2 Unit Risk for Air

7.3.2.1 Methodology for Quantitative Risk Estimates--The methodologies used to arrive at quantitative estimates of risk must be capable of being implemented using the data available in existing epidemiologic studies of exposure to airborne arsenic. In order to extrapolate from the exposure levels and temporal exposure patterns in these studies to those for which risk estimates are required, it will be assumed that the age-specific mortality rate of respiratory cancer per year per 100,000 persons for a particular 5-year age interval, i, can be represented using either of two models:

$$a_i(D) = a_i[1 + a'D^k] \qquad (1)$$

(a relative or multiplicative risk model), or

$$a_i(D) = a_i + 100{,}000a'D^k \qquad (2)$$

REC 5142

(an absolute or additive risk model). With either model, a_i is the age-specific mortality rate per year of respiratory cancer in a control population not exposed to arsenic, a' is a parameter representing the potential of airborne arsenic to cause respiratory cancer, and D is some measure of the exposure to arsenic up to the ith age interval. For example, D might be the cumulative dose in $\mu g/m^3$ years, the cumulative dose neglecting exposure during the last 10 years prior to the ith age interval, or the average dose in $\mu g/m^3$ over some time period prior to the ith age interval. The forms to be used for D will be constrained by the manner in which dose was treated in each individual epidemiologic study. The parameter k determines the shape of the dose-response curve. Attention will be given particularly to the values k = 1 and k = 2. If k = 1, the age-specific incidence rates vary linearly with the dose level (a linear model), and if k = 2 they vary quadratically. At low exposures the extra lifetime probability of respiratory cancer mortality will vary correspondingly (e.g., linearly for k = 1 and quadratically for k = 2).

The dose-response data available in the epidemiologic studies for estimating the parameters in these models consists primarily of a dose measure D_j for the jth exposure group, the person-years of observation Y_j, the observed number of respiratory cancer deaths O_j, and the number E_j of these deaths expected in a control population with the same sex and age distribution as the exposure group. The expected number E_j is calculated as

$$E_j = \sum_i Y_{ji} a_i / 100{,}000, \qquad (3)$$

where Y_{ji} is the number of person-years of observation in the ith age category and the jth exposure group ($Y_j = \sum_i Y_{ji}$). This is actually a simplified representation, because the calculation also takes account of the change in the

age-specific incidence rates with absolute time. The expected number of respiratory cancer deaths for the ith exposure group is

$$E(O_j) = \sum_i Y_{ji} a_i (1 + a' D_j^k)/100{,}000$$

$$= E_j (1 + a' D_j^k) \qquad (4)$$

under the relative risk model, and is

$$E(O_j) = \sum_i Y_{ji} (a_i + 100{,}000 a' D_j^k)/100{,}000$$

$$= E_j + a' Y_j D_j^k \qquad (5)$$

under the absolute risk model. Consequently, with either model, $E(O_j)$ can be expressed in terms of quantities typically available from the published epidemiologic studies. Note that person-years of observation are not required if the multiplicative model is used.

Making the reasonable assumption that O_j has a Poisson distribution, the parameters a' and k can be estimated from the above equations using the method of maximum likelihood. Once these parameters are estimated, the age-specific mortality rates for respiratory cancer can be estimated for any desired exposure pattern.

To estimate the corresponding additional lifetime probability of respiratory cancer mortality, let $b_1, \ldots, b_{18}$ be the mortality rates, in the absence of exposure, for all cases per year per 100,000 persons for the age intervals 0-4, 5-9,..., 80-84, and 85+, respectively; let $a_1, \ldots, a_{18}$ represent the corresponding rates for malignant neoplasms of the respiratory system. The probability of survival to the beginning of the ith 5-year age interval is estimated as

$$\prod_{j=1}^{i-1} [1 - 5b_j/100{,}000]. \qquad (6)$$

Given survival to the beginning of age interval i, the probability of dying of respiratory cancer during this 5-year interval is estimated as

$$5a_i/100{,}000. \qquad (7)$$

The probability of dying of respiratory cancer given survival to age 85 is estimated as a_{18}/b_{18}. Therefore, the probability of dying of respiratory cancer in the absence of exposure to arsenic is estimated as

$$P_0 = \sum_{i=1}^{17} [5a_i/100{,}000) \prod_{j=1}^{i-1} (1 - 5b_j/100{,}000)] + (a_{18}/b_{18}) \prod_{j=1}^{17} (1 - 5_{bj}/100{,}000) \qquad (8)$$

Here the mortality rates a_i apply to the target population for which risk estimates are desired, and consequently will be different from those in (1)-(5), which applied to the epidemiologic study cohort. If the 1976 U.S. mortality rates (male, female, white, and non-white combined) are used in this expression, then $P_0 = 0.0451$.

To estimate the probability P_{EP} of respiratory cancer mortality when exposed to a particular exposure pattern EP, the formula (8) is again used, but a_i and b_i are replaced by $a_i(D_i)$ and $b_i(D_i)$, where D_i is the exposure measure calculated for the ith age interval from the exposure pattern EP. For example, if the dose measure used in (1) is cumulative dose to the beginning of the ith age interval in $\mu g/m^3$-years, and the exposure pattern EP is a

lifetime exposure to a constant level of 10 μg/m^3, then $D_i = (i-1)(5)(10)$, where the 5 accounts for the fact that each age inverval has a width of 5 years. The additional risk of respiratory cancer mortality is estimated as

$$P_{EP} - P_0. \qquad (9)$$

If the exposure pattern EP is constant exposure to μg/m^3, then $P_{EP} - P_0$ is called the "unit risk."

This approach can easily be modified to estimate the extra probability of respiratory cancer mortality by a particular age due to any specified exposure pattern. It is also clear that the applications of the approach are not limited to respiratory cancer.

7.3.2.2 Risk Estimates from Epidemiologic Studies--Prospective studies of the relationship between mortality and exposure to airborne arsenic have been conducted for the Anaconda, Montana smelter (Lee and Fraumeni, 1969; Lee-Feldstein, 1983; Higgins et al., 1982; Brown and Chu, 1983 a, b, c); and the Tacoma, Washington smelter (Pinto et al., 1977; Enterline and Marsh, 1982).

The study of Lee-Feldstein (1983) reported on an additional 14 years of follow-up of the cohort of 8047 studied by Lee and Fraumeni (1969), and used essentially the same methods of analysis as the earlier study. Therefore, it will not be necessary to consider the Lee and Fraumeni study in any detail in this report. Higgins et al. (1982) followed for an additional 14 years a sample of 1800 men from the cohort studied by Lee and Fraumeni, but used different exposure classifications and different methods of analyses.

Brown and Chu (1983 a, b, c), in a series of papers, arranged the Anaconda smelter data in such a manner that a mathematical model could be derived from it to account for the effect of the timing of exposure as predicted by the multistage model.

REC 5146

Whereas Pinto et al. (1977) studied a cohort from the Tacoma smelter consisting of 527 men followed only after retirement, the study by Enterline and Marsh (1982) involved 2802 men and included follow-up prior to retirement. Consequently, the Enterline and Marsh study appears to provide a stronger basis for quantitative risk assessment than the Pinto et al. study.

In addition to studies of copper smelter workers, there have also been studies of workers exposed to arsenicals in the production or use of pesticides. Ott et al. (1974) studied the mortality experience of workers exposed to lead arsenate and calcium arsenate.

7.3.2.2.1 The Lee-Feldstein (1983) study. This study included 8047 white males who were employed as smelter workers for 12 months or more before 1957, and whose mortality experience was observed from 1938 through 1977. Altogether, the study involved 192,476 person-years of follow-up and 3550 deaths, including 302 from respiratory cancer (Table 7-21). Expected numbers of cancer deaths were calculated on an age-adjusted basis using the combined mortality experience of the white male population of Idaho, Wyoming, and Montana. As Table 7-21 indicates, malignant neoplasms of the digestive and respiratory tracts had SMRs of 125 and 285, respectively, both of which were significant at the 1 percent level (SMR = [observed/expected][100]).

Workers were categorized both by duration of employment and level of exposure to airborne arsenic in order to determine the effect of these parameters upon mortality. For each year of the study period, workers were assigned to one of five groups on the basis of total years of smelter employment completed (Table 7-22). Work areas in the smelter were divided into heavy, medium, or light exposure areas. Based upon this division, workers were categorized into heavy, medium, or light exposure groups, as determined by their maximum exposure for 12 or more months. The results for respiratory cancer based upon these categorizations are given in Table 7-23.

5 (1 to 4 years)	3248	1006	88,279
TOTAL	8045	3522	192,476

[a]Employees in all cohorts were living on Jan. 1, 1938.

[b]Group assignment of each person here was based on his status at the termination of employment or on September 30, 1977 (whichever date was earlier).

[c]Represents cumulative follow-up experience over the study period, 1938-77, with a total of 67,569 person-years of follow-up in the period 1964-77. Individuals were initially counted at risk upon completing 1 year of employment or on Jan. 1, 1938, if employed at least a full year before that date. In each calendar year of the study period, employees were counted in the group reflecting their cumulative work experience to date.

Source: Lee-Feldstein (1983).

Exposure to airborne arsenic was estimated from 702 samples collected at 56 sampling stations during the years 1943-1958 (Morris, 1975). Morris estimated that airborne levels averaged 11.27, 0.58, and 0.27 mg/m^3 in the heavy, medium, and light exposure areas, respectively. Respirators were used with varying degrees of faithfulness in the high exposure areas; consequently, average individual exposures in these areas were probably much less than 11.27 mg/m^3. A rough estimate is that use of respirators reduces the exposure levels by a factor of 10 (OSHA, 1978).

Source: Adapted from Lee-Feldstein (1983).

The Lee-Feldstein (1983) study has a number of features which support its use in making quantitative estimates of respiratory cancer risk from airborne arsenic. It was a large study that involved observations of a considerable number of respiratory cancer deaths. A substantial amount of follow-up was conducted of persons who had been exposed for 15 years or more. Estimates of exposure levels and work histories are available for estimating individual exposures and for determining dose response.

It would have been more appropriate for making quantitative estimates of risk to have categorized workers by their individual cumulative or average exposures, rather than by their maximum exposures for 1 year or more. In developing the quantitative estimates, it will be assumed that a worker's average exposure during work hours was equal to the exposure for the category to which he was assigned. However, because these assignments were based upon

maximum exposures for at least a 12-month period, this approach tends to overestimate exposures, and consequently, to underestimate the carcinogenic potency of arsenic.

Because smoking is also an important risk factor for respiratory cancer, it would have been very useful to have smoking histories for the workers. Higgins et al. (1982) collected some limited smoking data for this cohort. Higgins and co-workers suggest that the smelter workers smoked somewhat more than the average U.S. white male population, but the difference was not enough to have a major effect upon the outcome of the study.

Development of risk estimates: The data from the Lee-Feldstein (1983) study used in the risk assessment are listed in Table 7-24. The relative risk (observed/expected) from this table are graphed in Figure 7-2, and the absolute risks ([observed-expected/person-years) in Figure 7-3. It is clear from these graphs that the risk for the high-exposure group exposed for greater than 25 years is not commensurate with the risks for the other groups. Because of this, and also because the exposures in the high exposure groups are much more uncertain than those of the other groups, it was decided to estimate risk using only the low and medium exposure groups. Results of applying chi-square goodness-of-fit tests of the relative and absolute risk models with $k = 1$ and $k = 2$ are recorded in Table 7-25. The maximum likelihood estimates of the carcinogenic potency parameter a' are also listed in this table. The maximum likelihood fits of these models are graphed in Figures 7-2 and 7-3. All of the fits are poor (p less than 0.0001) with the exception of that for the absolute-risk model; this latter fit is marginally acceptable ($p = 0.025$).

The unit risk (additional risk of respiratory cancer death from lifetime exposure to 1 $\mu g/m^3$ airborne arsenic) obtained from the absolute-risk model with $k = 1$ is also listed in Table 7-25. This risk was estimated by applying (2), (8), and (9) with D_i based upon a constant exposure of 1 $\mu g/m^3$.

REC 5151

(less than	Heavy	5973	6520	11	2.4
15 years of	Medium	3074	24594	31	9.3
exposure)	Light				

[a]Exposures are in $\mu g/m^3$-years estimated as (air concentration)(duration). For light, medium, and heavy exposures, air concentration was estimated as 290, 580, and 1127 $\mu g/m^3$, respectively (OSHA, 1978). Duration was estimated as follows (cf. Table 7-22):

Cohort 1: Persons in this cohort had at least 25 years' exposure. If all had worked continuously throughout follow-up, average duration would have been 25 + 27053/1899 = 39 years. Therefore the midpoint (39 + 25)/2 = 32 years was used.

Cohort 2: The midpoint of the employed interval, i.e., (15 + 25)/2 = 20 years was used.

Cohort 3: A weighted average of the midpoints of the employment intervals, i.e.,

$$\frac{(3)\ (88279) + (7.5)(30854) + (12.5)(19734)}{88279 + 30854 + 19734} = 5.3 \text{ years was used.}$$

[a] Potencies are in different units, depending upon model used (see text), and consequently are not comparable.

[b] Additional lifetime risk of respiratory cancer mortality from lifetime environmental exposure to 1 $\mu g/m^3$ arsenic.

[c] 6.04(E-7) means 6.04×10^{-7}.

[d] p-value of chi-square goodness-of-fit test is less than 0.01.

REC 5155

Specifically,

$$D_i = 4.56[(i-1) + 2.5] \qquad (10)$$

was used, which represents the cumulative exposure in $\mu g/m^3$ resulting from a constant exposure to $\mu g/m^3$ from birth to the midpoint of the ith 5-year age interval. The factor 4.56 is needed to account for the fact that the workers in the occupational study used to estimate the carcinogenic potency of arsenic were only exposed during work hours. Assuming that workers were exposed for an average of 8 hours per day, 240 days per year, an environmental exposure to 1 $\mu g/m^3$ for 1 year is equivalent to an occupational exposure to

$$(1\ \mu g/m^3)(24\ \text{hours}/8\ \text{hours})(365\ \text{days}/240\ \text{days}) = 4.56\ \mu g/m^3 \qquad (11)$$

for 1 year.

7.3.2.2.2 The Higgins et al. (1982) study. Higgins et al. conducted additional independent follow-up through 1977 of a sample of 1800 men from the Anaconda smelter cohort studied by Lee and Fraumeni (1969). The sample included all of the men classified in the heavy exposure category by Lee and Fraumeni (1969), as well as a random sample of 20 percent of the remaining cohort. There were 80 deaths from respiratory cancer in the sample. Expected numbers were based upon the mortality rates of Montana white males, except for "all respiratory diseases"; U.S. white males were the referenced population for the latter category.

Higgins et al. also reviewed the industrial hygiene data and calculated average concentrations for the period 1943-1965 for 18 departments. No measurements were available for 17 departments, and average concentrations were estimated for these. These estimates were coupled with work histories

REC 5156

updated through 1978 to obtain exposure measures for each individual in the study. Three types of individual exposure measures were considered: ceiling, time-weighted average (TWA), and cumulative. Ceiling exposures were estimates, in $\mu g/m^3$, of the highest exposure a man experienced for 30 days or more. TWA exposures were estimates, in units of $\mu g/m^3$, of the time-weighted average exposures during the period of employment. Cumulative exposures were estimates of total exposure in units of $\mu g/m^3$-years.

Higgins et al. investigated 5 combinations of follow-up and time period during which exposure was assessed: I. Exposure was assessed up to the date a worker entered the study and follow-up was from entry into the study through 1978; II. Exposure was assessed up to 1964 and follow-up was also through this date; III. Exposure was assessed through 1964 and follow-up was through 1978; IV. Exposure was assessed through 1964 and follow-up was from 1964 through 1978; V. Exposure was assessed through 1978 and follow-up was also through 1978. These different methods were considered principally because of the perceived difficulties of overlapping exposure and follow-up periods. Thus, with methods I and IV, exposure and follow-up periods were disjoint, whereas with methods II and V they coincided.

The analyses based upon ceiling exposures are not considered suitable for quantitative risk assessment because it seems extremely unlikely that respiratory cancer risk would be a function of peak exposures for any 30-day period, regardless of the other exposures that might have been experienced. This is also the case with the TWA analyses, because the exposures were averaged only over the period of employment, without regard to the duration of employment. If either of these dose measures were appropriate, it would mean, for example, that exposure to 500 $\mu g/m^3$ for 1 month would produce the same risk as exposure to 500 $\mu g/m^3$ for 30 years--which seems highly unlikely.

Thus, the analyses of Higgins et al. which appear to be most appropriate for developing quantitative estimates are those based upon cumulative exposure. This particular type of analysis was applied only to method V and applied only in Higgins (1982). The results of this analysis for lung cancer are listed in Table 7-26.

TABLE 7-26. RESPIRATORY CANCER MORTALITY 1938-1978 FROM CUMULATIVE EXPOSURE TO ARSENIC FOR 1800 MEN WORKING AT THE ANACONDA COPPER SMELTER[a]

Cumulative Exposure $\mu g/m^3$-years	Person-Years of Observation	Observed Deaths	Expected Deaths
0-500 (250)[b]	13845.9	4	5.8
500-2000 (1250)	10713.0	9	5.7
2000-12000 (7000)	11117.8	27**	6.8
≧ 12000 (16000)	9015.5	40**	7.3

[a]From Higgins (1982), Table 6.

[b]Numbers in parenthesis indicate assumed average exposures.

**Significant at 0.01 level.

Information on the smoking habits of 80.6 percent of the 1800 men was obtained from questionnaires administered directely to those still living and to close friends or relatives of those who were deceased. Sixteen percent of the smelter workers were "non-smokers" compared with 24-36 percent of U.S. males from 1955 through 1978. Thus, it appears that the smelter workers smoked somewhat more than the average U.S. male. However, no confounding was detected between arsenic exposure and smoking; 15.1 percent of those in the "heavy" exposure group were non-smokers, versus 16.3 percent in the other

REC 5158

TR 1843

exposure groups. Significant increases in respiratory cancer were observed even among non-smokers exposed to high levels of arsenic.

Development of risk estimates: The relative risks (observed/expected) from Table 7-26 are graphed in Figure 7-4, and the absolute risks ([observed-expected]/person-years) in Figure 7-5. Results of applying chi-square goodness-of-fit tests of the relative- and absolute-risk models with $k = 1$ and $k = 2$ are recorded in Table 7-25. The maximum likelihood estimates of the carcinogenic potency parameter a' are also listed in Table 7-25. The maximum likelihood fits of those models are graphed in Figures 7-4 and 7-5. The fits for $k = 1$ are both excellent, with the absolute-risk model providing a slightly better fit than the relative-risk model ($p = 0.75$ vs. $p = 0.46$). The fits for $k = 2$ are much less adequate ($p = 0.017$ for the absolute-risk model and $p = 0.0015$ for the relative-risk model).

The unit risks (defined as the additional risk of respiratory cancer death from lifetime exposure to 1 $\mu g/m^3$ airborne arsenic) obtained from the absolute- and relative-risk models with $k = 1$ are also listed in Table 7-25.

These risks were estimated by applying (1) or (2), (8), and (9) with D_i based upon a constant exposure of 1 $\mu g/m^3$. Specifically,

$$D_i = (4.56)(72) \qquad (12)$$

was used, which represents the average lifetime cumulative exposure in $\mu g/m^3$ resulting from a constant exposure to 1 $\mu g/m^3$. Average lifetime exposure is used because it seems most commensurate with the treatment of exposure by Higgins et al.; in their analysis all of the person-years attributable to a single worker were placed into a single exposure category based upon total lifetime exposure, and consequently person-years of observation were placed into exposure categories according to exposures which had not yet occurred. It

REC 5159

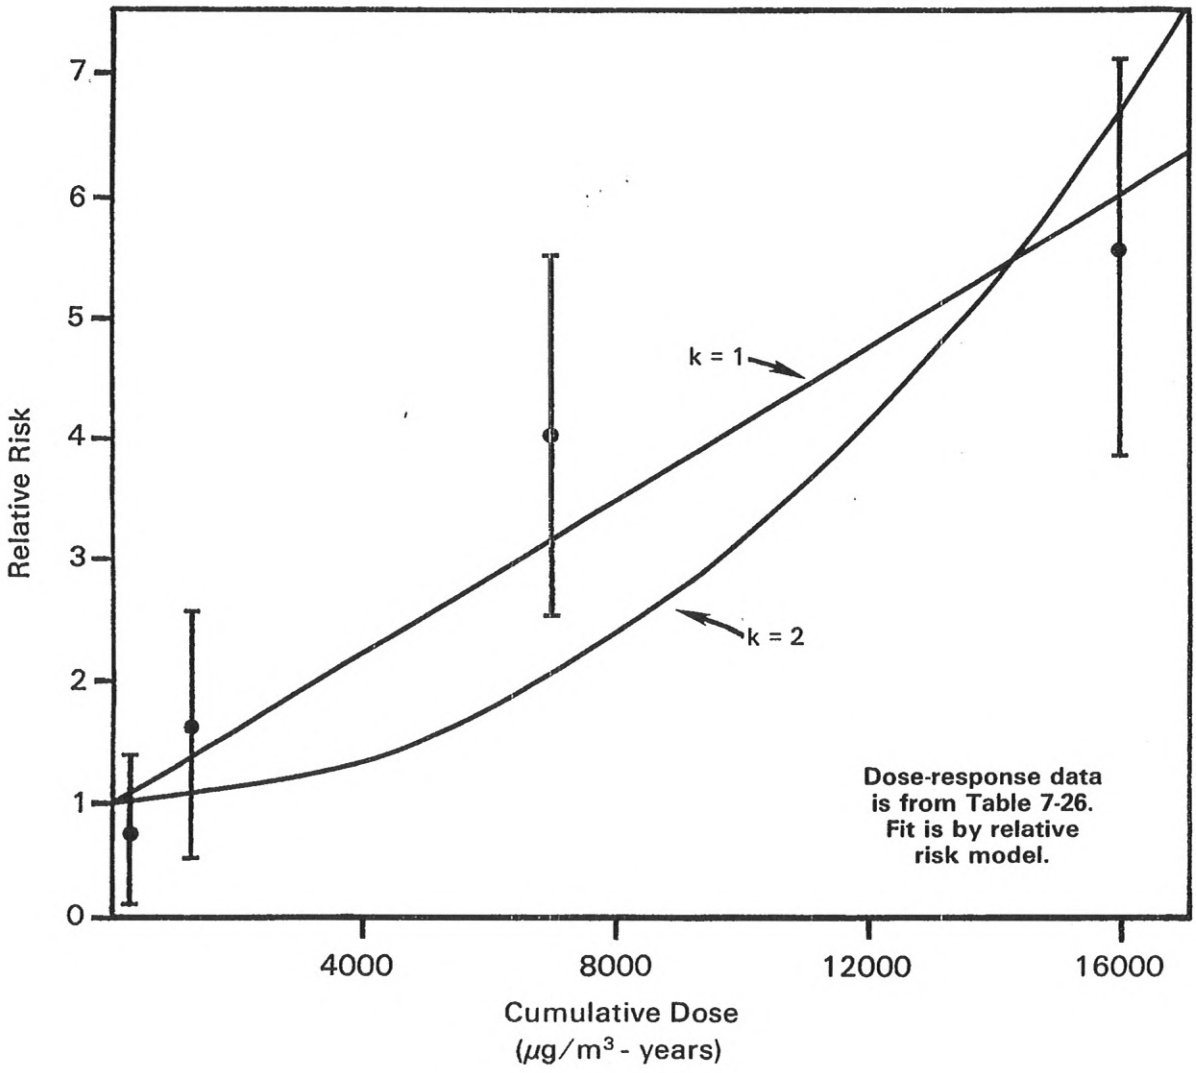

Figure 7-4. Relative risks and 90% confidence limits for data of Higgins (1982).

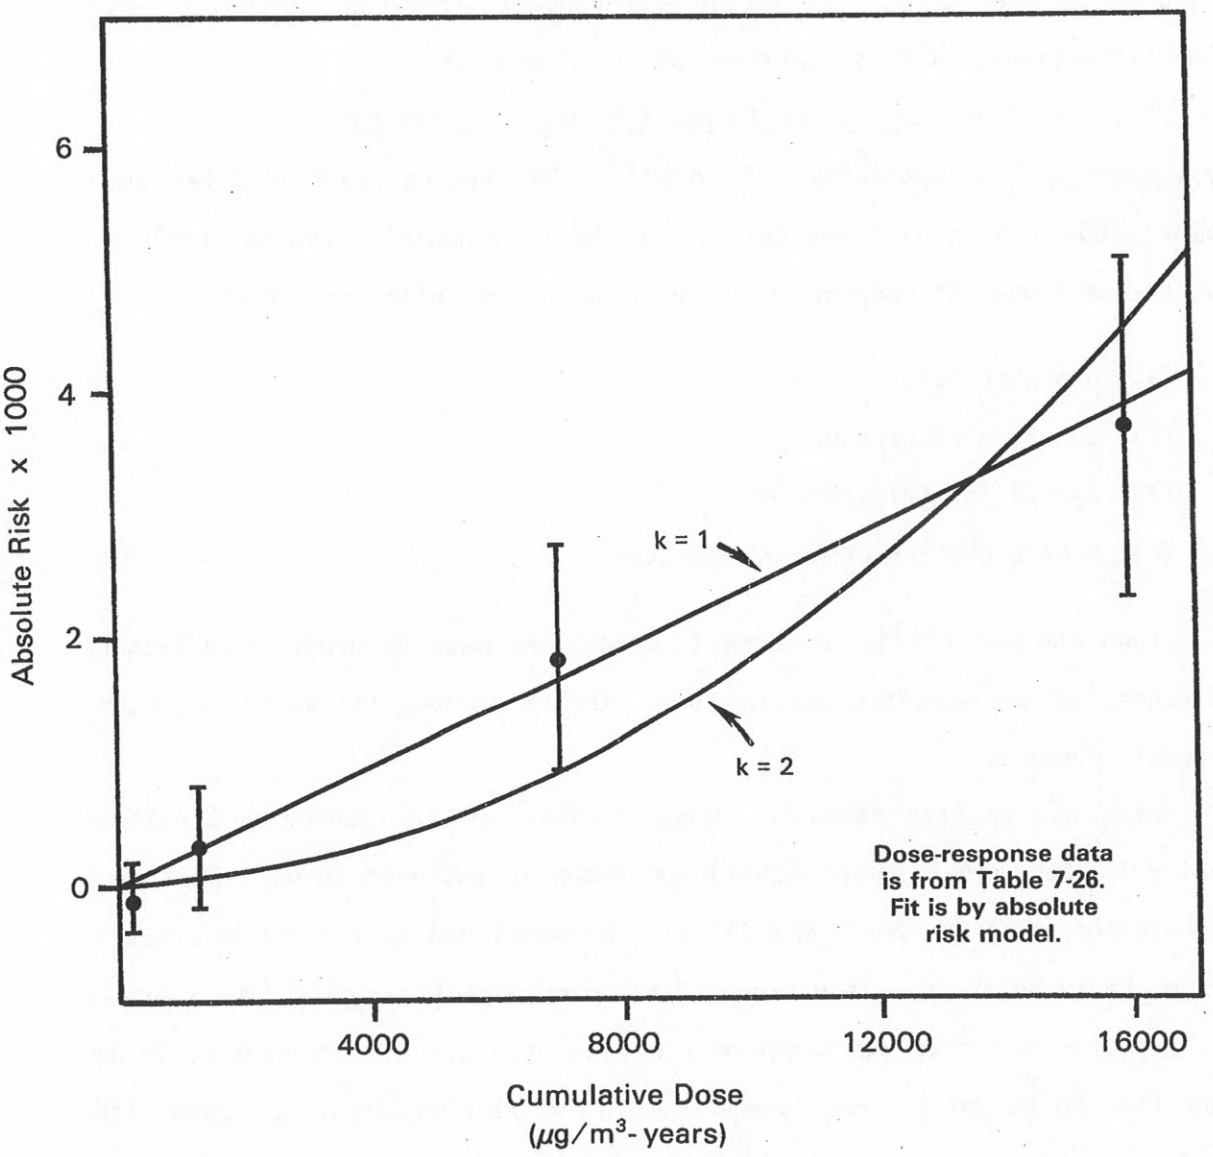

Figure 7-5. Absolute risks and 90% confidence limits for data of Higgins (1982).

would have been more appropriate for purposes of quantitative risk assessment had exposures been related to each 5-year age interval (as was done in the analysis of Enterline and Marsh, 1982) rather than to the total observation period of an individual. The factor 4.56 converts from occupational to environmental exposures and is explained at equation (11).

7.3.2.2.3 The Brown and Chu estimates from the Anaconda data. Development of Risk Estimates. As noted by Whittemore (1977) and Day and Brown (1980), the multistage theory for the carcinogenic process predicts that the carcinogenic response is a function of the following factors:

(1) exposure rate

(2) duration of exposure

(3) age at initial exposure

(4) time since cessation of exposure.

Brown and Chu (1983a) discuss in detail the ways in which these factors influence the age-specific carcinogenic rate at various stages of the carcinogenic process.

Using the updated Anaconda copper smelter workers cohort originally studied by Lee and Fraumeni (1969) and recently extended through 1977 by Lee-Feldstein (1983), Brown and Chu (1983b) concluded that airborne arsenic most probably acted on a late stage of the carcinogenic process. As a result, they hypothesized that the carcinogenic risk from arsenic exposure could be quantified by assuming a multistage model in which only the penultimate stage is affected by exposure. Under this assumption, the risk may be expressed in the form

$$r(d, t_o) = C[(d + t_o)^{k-1} - t_o^{k-1}] \qquad (13)$$

REC 5162

where d is the duration of exposure, t_o is the age at initial exposure, and C and k are unknown parameters. The parameter C depends upon the exposure rate, and the parameter k upon the time effect of exposure.

Brown and Chu (1983b) noted a deviation from this model on the part of workers who left employment at the copper smelter before the age of 55. As a result, the mortality experience of that group after leaving employment was not included in the analysis.

In order to estimate the unknown parameters C and k, the basic mortality data were arranged in the three-way table reproduced as Table 7-27. The three classifications used in this table are as follows:

(1) Level of exposure, corresponding to Lee and Fraumeni (1969)--classified into heavy, medium, and light exposure groups;

(2) Duration of employment, classified into the following five subgroups; 0-9, 10-19, 20-29, 30-39, and 40+ years;

(3) Age at initial employment, classified into the following five subgroups; 20, 20-29, 30-39, 40-49, and 50+ years.

For each of the 3 x 5 x 5 = 75 cells in the table, the following three variables were given:

Obs = observed number of respiratory cancer deaths;

Exp = expected number of respiratory cancer deaths (based upon the U.S. white male age-specific calendar-time-specific respiratory cancer mortality rates); and

Pyr = person-years of observation

A single individual could supply information for more than one cell as his duration of employment increased over the follow-up period. The person-year weighted average duration of employment, and age at initial employment, were calculated for each cell.

Assuming that age at initial exposure is equivalent to age at initial employment, and that duration of employment and exposure are equivalent, Brown and Chu (1983c) fitted equation 13 to the data in Table 7-27. They used the maximum likelihood method, assuming a binomial distribution where Obs is the number of positive responses, Pyr is the sample size, and the rate of response is $p = Exp/Pyr + r(\bar{d},\bar{t}_o)$, where $\bar{d},\bar{t}_o$ are the averages for each cell. Using this approach, the value for k is estimated to be 6.8, and c = .603, 1.42, 1.74×10^{-13} for the light, medium, and heavy exposure categories, respectively.

Brown and Chu (1983c) did not attempt to give an exposure rate estimate to the heavy, medium, and light exposure groups of Lee and Fraumeni, (1969). One reason for this was that "heavy" and "medium" were defined as "having worked at least one year in a heavy or medium exposure area." The "total time worked" was not necessarily an indication of the total time worked in a heavy or medium exposure area. As a result, the use of the exposure rate in the areas defined as medium or heavy would tend to overestimate the true average exposure over an individual's working history. This bias did not exist for those in the light exposure group, since almost all of their working time was spent in light exposure areas. In addition, these low environmental exposures are of greater utility in estimating risks.

As a result of these factors, only the light exposure group was used to obtain a dose-response model. In this group, Brown and Chu (1983c) estimated that the respiratory cancer rate for an individual first exposed at age t_o for a duration of d years would be

$$r(d,t_o) = .603 \times 10^{-13} [(d + t_o)^{5.8} - t_o^{5.8}]. \qquad (14)$$

Only limited information exists concerning the time-weighted exposure of workers in the light exposure areas. Arsenic concentrations in several light

exposure areas, as given in a NIOSH criteria document (1975), are shown in Table 7-28.

In the absence of information to the contrary, it is assumed that the person-hours spent in each area are equal. Thus an estimate of the time-weighted average for workers in the light exposure category is

$$1/3 \times .7 + 1/3 \times .17 + 1/3 \times .004 = .291 \text{ mg As/m}^3.$$

Under the linear assumption, equation 14 may be expressed in terms of mg As/m^3 working exposure by dividing by .291, which gives the result

$$r(d,t_o) = 2.07 \times 10^{-13} [(d + t_o)^{5.8} - t_o^{5.8}]. \qquad (15)$$

REC 5167

TR 1852

In this case, exposure is expressed in mg As/m^3 per 8-hr working day. To change the relationship so that it expresses the risk due to a lifetime of continuous exposure to 1 ug As/m^3, we assume 240 days worked per year, one mg As/m^3 on the job gives the same cumulative exposure as 10^3 x $1/3 \times \frac{240}{365} = 219$ µg As/m^3 continuous exposure.

The age-specific rate due to a continuous 1 µg As/m^3 exposure is obtained by substituting $t_o = 0$ and $d = t$ = age into equation (15) and dividing by 219 to arrive at the correct number of exposure units. This gives the result

$$r(t) = 9.45 \times 10^{-16} \, t^{5.8}. \qquad (16)$$

The unit risk is approximately equivalent to the risk of induced respiratory cancer in the median life span. Based upon 1976 U.S. vital statistics, the median life span is 76.2 years, so that the unit risk is expressed approximately as

$$p \simeq \int_o^{76.2} 9.45 \times 10^{-16} \, t^{5.8} = \frac{9.45}{6.8} (76.2)^{6.8} \times 10^{-16} = 8.71 \times 10^{-4}. \qquad (17)$$

An additional approximation consistent with the previous unit calculations is obtained by assuming that

$$r(t) = 9.45 \times 10^{-16} \left[\frac{t_j + t_{j-1}}{2}\right]^{5.8} \quad t_{j-1} < t < t_j \qquad (18)$$

where t_j are the ages at the interval boundaries given in U.S. vital statistics records. This assumes that the age-specific death rate due to the exposure is constant throughout the interval and equal to the true value at the midpoint of the interval. Under this approximation, using 1976 vital statistics, the unit risk is estimated to be $P \simeq 1.25 \times 10^{-3}$.

REC 5168

Evaluation of Goodness-of-Fit. It is desirable to assess whether the data for the low-exposure group is consistent with the model utilized to estimate the unit risk. However, two factors tend to create a situation that would decrease this goodness-of-fit and bias the results. First, the exact values for each cell of $\bar{d}$, $\bar{t}_o$ are presently not available. Second, the value of k was determined on the basis of all three exposure groups, and does not give as good a fit as would be obtained using the low-exposure group alone.

Brown states (personal communication, 1983) that the exact values of $\bar{d}, \bar{t}_o$ are very close to the midpoint of the interval, and that the values of k appear to be statistically consistent between exposure groups. Thus, distortions of the data because of the use of midpoint values and average k, although inevitable, are not appreciable.

The expected number of cases in each cell are calculated using the relationship

$$E = Exp + Pyr \times .603 \times 10^{-13} [(d + t_o)^{5.8} - t_o^{5.8}], \qquad (19)$$

in which Exp and Pyr are taken from Table 7-27 and d, t_o are the midpoints of the intervals. These results are shown in Table 7-29. A standard chi-square goodness-of-fit test is then run, resulting in a chi-square value of $X^2_{21} = 13.85$ with $23.2 = 21$ degrees of freedom and an associated p-value of .88. Unfortunately, due to the low expected number of cases in many of the cells, the X^2 approximation is of questionable validity for this situation.

To obtain a more stable approximation, cells with low frequency that are as close as possible to each other are usually combined. It is important to have some criteria for combining the data that do not depend upon inspection of the data itself. Two methods of combining the data are used here. The first is across columns (duration exposed), so that the maximum number of

TABLE 7-29. OBSERVED AND EXPECTED NUMBER OF RESPIRATORY CANCER DEATHS FOR EACH CELL IN THE LOW-EXPOSURE GROUP OF TABLE 7-27

	d				
t_o	5	15	25	35	45

55	3 2.582	2 1.234	0 .418		

$X^2_{21} = 13.85$, $p = .88$

cells are obtained, with the constraints that combined cells must have at least three expected cases, and that all cells combined are consecutive within a row. The second approach uses the same technique within a column (age first exposed). The results are shown in Tables 7-30 and 7-31 respectively, giving chi-square values of 7.01 and 7.61, with p-values of .41 and .38. Thus the assumed model is shown to be consistent with the observed low-exposure data.

7.3.2.2.4 The Enterline and Marsh (1982) study. This study included all men (2802 in all) employed at the Tacoma, Washington copper smelter for a year or more during 1940-1964. Their mortality experience was observed through 1976. The study involved over 70,000 person-years of observation, and 104 deaths from cancer of the respiratory system were recorded (Table 7-32). Respiratory cancer deaths had an SMR of 189.4, which was significantly increased at the 1 percent level. Expected deaths for Table 7-32 were based upon U.S. white

male mortality rates. The respiratory cancer SMR increases to 198.1 when Washington State mortality rates are applied.

Enterline and Marsh estimated individual exposures to airborne arsenic using individual work histories, urine arsenic measurements, and an estimated correlation between exposure to airborne arsenic and resulting levels of arsenic in urine. Average urine arsenic levels were available by department for the years 1948-52, 1973, 1974, and 1975. Linear interpolations were used to estimate levels between 1952 and 1973. Levels during 1949-1952 were assumed to hold prior to that time. By coupling these data with employee work histories, Enterline and Marsh estimated individual cumulative exposures for various times in units of μg-years/ℓ urinary arsenic.

Pinto et al. (1977) compared airborne concentrations of arsenic with urinary arsenic levels for 24 workers wearing personal air samplers for 5 successive days. A regression analysis of these data showed a highly significant linear correlation between airborne and urinary arsenic ($p < 0.01$). Average airborne arsenic in units of μg/m^3 was estimated to be 0.304 times average urinary arsenic levels in units of μg/ℓ.

To investigate dose-response, Enterline and Marsh divided the total person-years of observation into 5 groups by cumulative arsenic exposure (0 lag), and also by cumulative arsenic exposure up to 10 years prior to the year of observation (10-year lag). In this type of analysis, as a worker continues to be exposed to arsenic, he or she will contribute person-years to progressively higher exposure categories. The numbers of respiratory cancer deaths and corresponding expected numbers for each of these groups are given in Table 7-33. In this table, urinary arsenic levels provided by Enterline and Marsh have been converted to airborne exposures in μg/m^3-years, using the factor 0.304 estimated by Pinto et al. (1977). The observed numbers of cancers are all significantly increased at the higher exposure levels.

[a]Exposures are in $\mu g/m^3$-years estimated by the formula (I $\mu g/l$-years) (0.304) where I is mean urinary exposure index from Enterline and Marsh (1982) Table 8 and 0.304 is the relation between urinary and airborne arsenic estimated by Pinto et al. (1977).

[b]Furnished by Dr. Enterline (personal communication).

Although the Enterline and Marsh (1982) study is not as large as that of Lee-Feldstein (1983), it does involve a sizable number of respiratory cancer deaths (104). Workers were followed for an extended period--an average of 25 years per individual. Several features of the analysis render it more amenable to quantitative risk estimation than the analysis used by Lee-Feldstein. Enterline and Marsh made estimates of individual exposure histories, whereas Lee-Feldstein did not. The type of dose-response analysis used by Enterline and Marsh is also more suitable for quantitative risk estimation. The exposure estimates based on a 10-year lag probably yield a more realistic dose response than those that do not utilize a lag. Because the latency period for respiratory cancer is generally greater than 10 years (cf. Doll and Peto,

REC 5174

1978), exposure during the last 10 years prior to observation would not be expected to affect respiratory cancer mortality.

By applying urinary arsenic measurements made during the years 1948-52 to earlier years, Enterline and Marsh probably underestimated exposures prior to 1948. This would result in an overestimate of the carcinogenic potency of arsenic. A calculation by Enterline and Marsh of SMRs by both year of hire and cumulative exposure indicates that workers in a given cumulative exposure category tend to have at least roughly comparable SMRs irrespective of the year of hire. This suggests that exposure estimates for earlier years are not greatly in error. However, further investigation of this problem would be useful.

Because smoking is also an important risk factor for respiratory cancer, it would have been helpful if data on smoking habits had been available for analysis. Pinto and Enterline (undated) report on smoking histories obtained in 1975 from 550 active employees at the Tacoma smelter. Of these employees, 59.6 percent were active smokers, compared to 45.4 percent in 1970 for U.S. males aged 21-64. If this excess of smokers holds in general for the smelter workers, then a small fraction of the excess in respiratory cancer could have been due to smoking.

Development of risk estimates: The data from Table 7-33 were used for quantitative risk assessment. The relative risks (observed/expected) from this table are graphed in Figures 7-6 and 7-7, and the absolute risks ([observed- expected]/person-years) in Figures 7-8 and 7-9. Although there is no clear trend of increasing SMRs with increasing exposures, such a trend is present for absolute risk. Results of applying chi-square goodness-of-fit tests of the relative- and absolute-risk models with $k = 1$ and $k = 2$ are recorded in Table 7-25. The maximum likelihood estimates of the carcinogenic

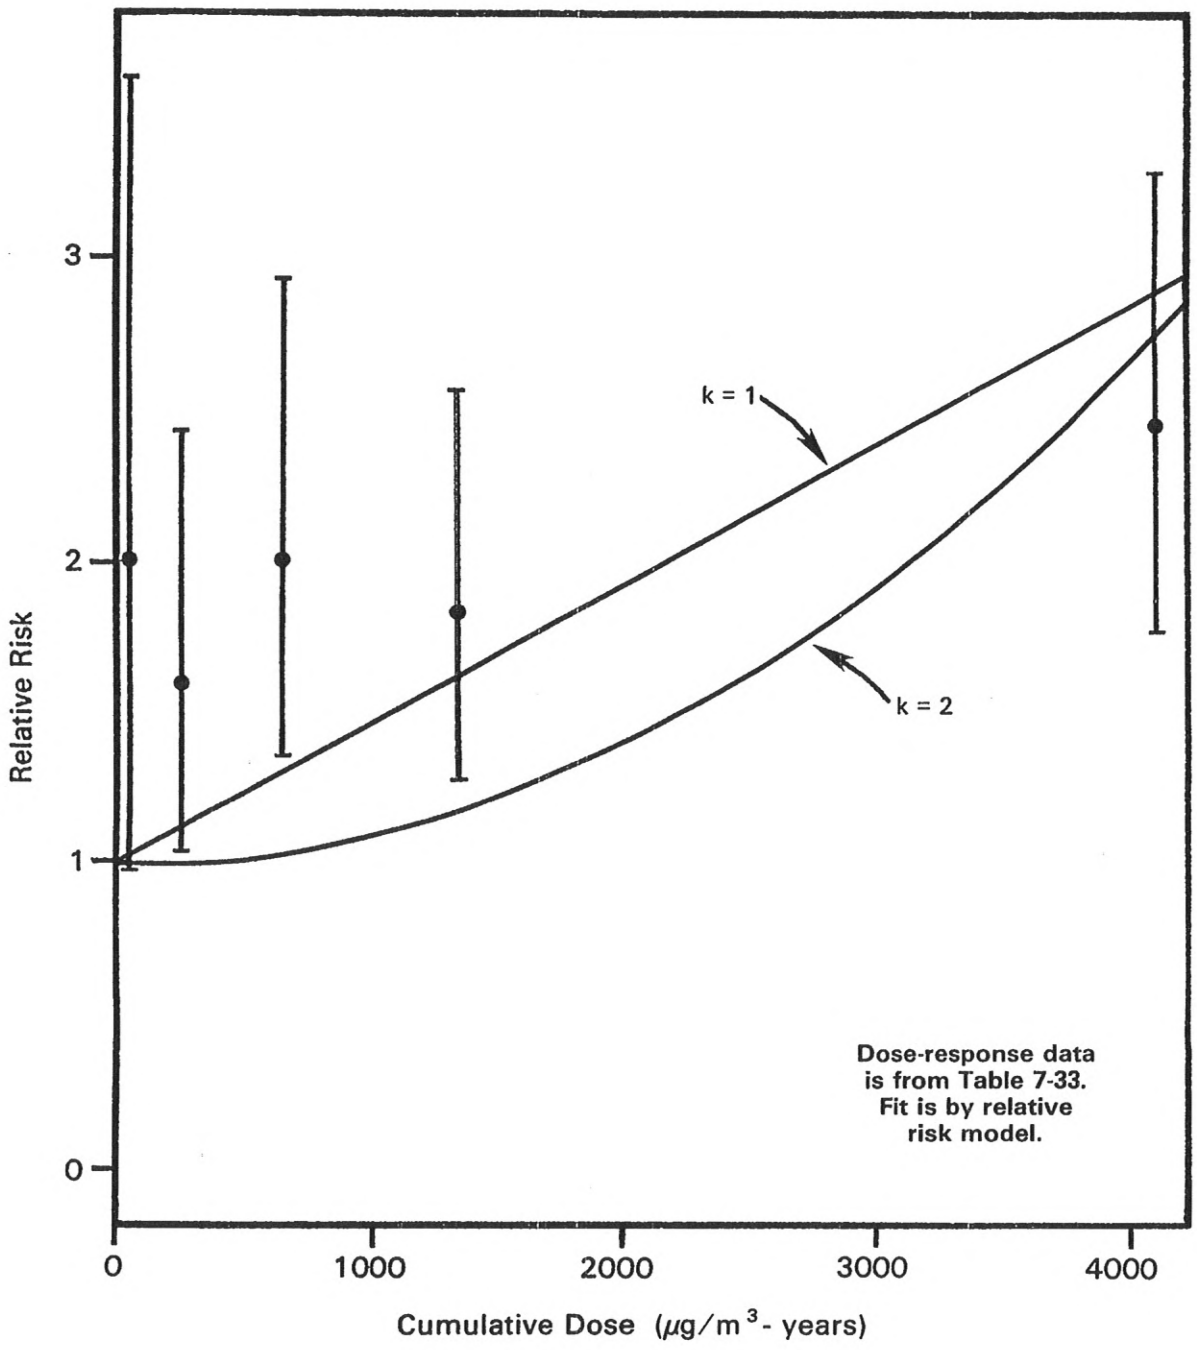

Figure 7-6. Relative risks and 90% confidence limits for zero-lag data of Enterline and Marsh (1982).

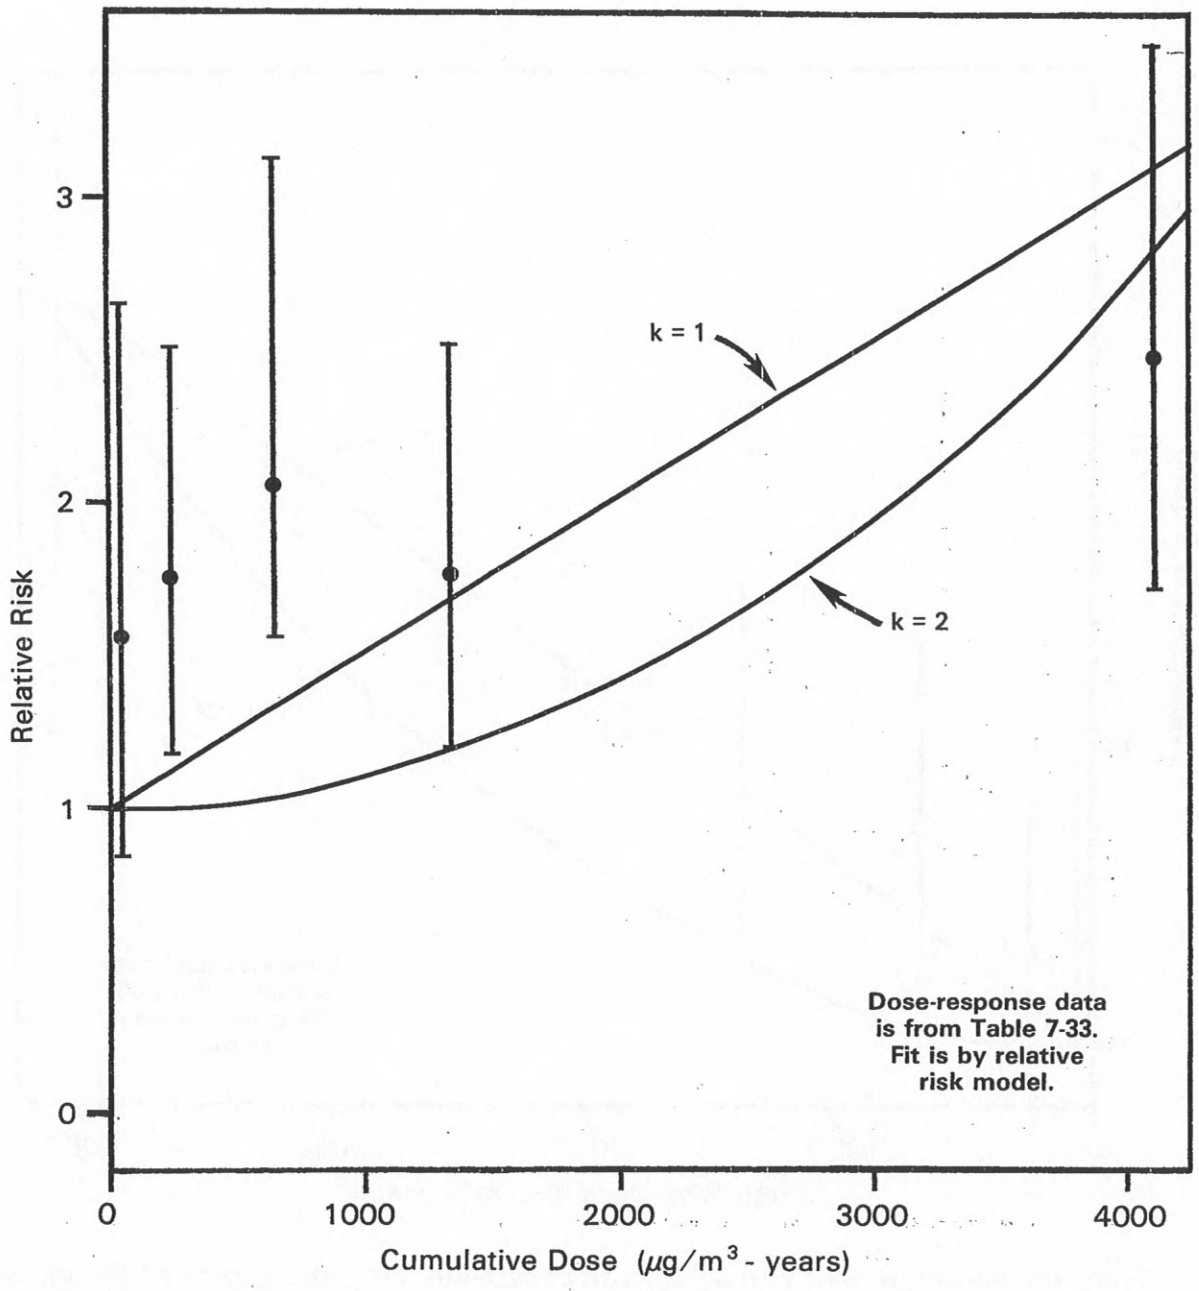

Figure 7-7. Relative risks and 90% confidence limits for 10 year lag data of Enterline and Marsh (1982).

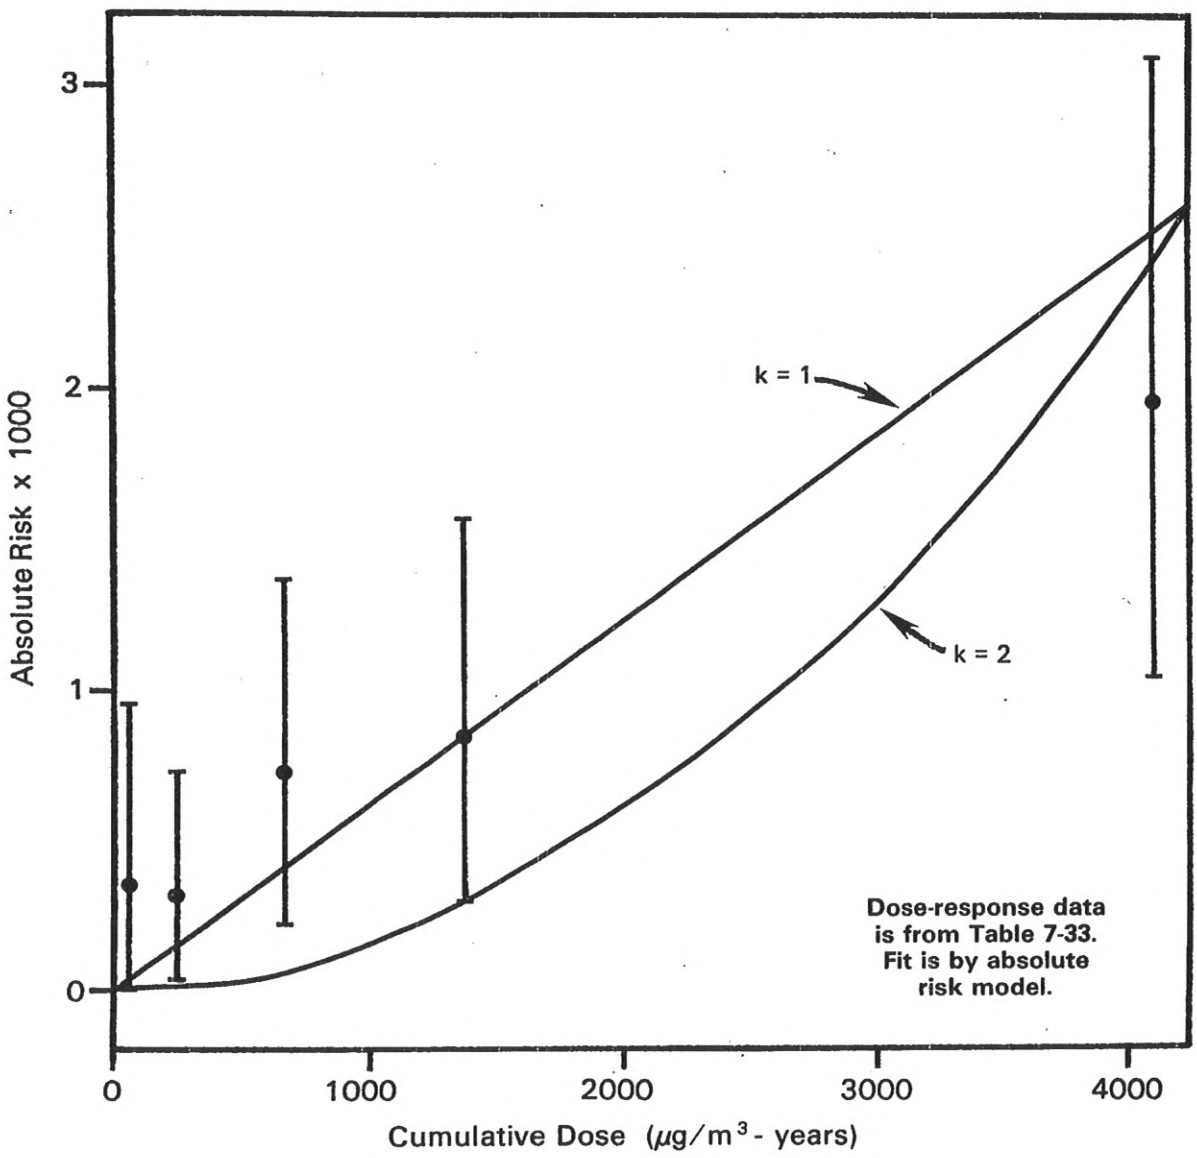

Figure 7-8. Absolute risks and 90% confidence limits for zero-lag data of Enterline and Marsh (1982).

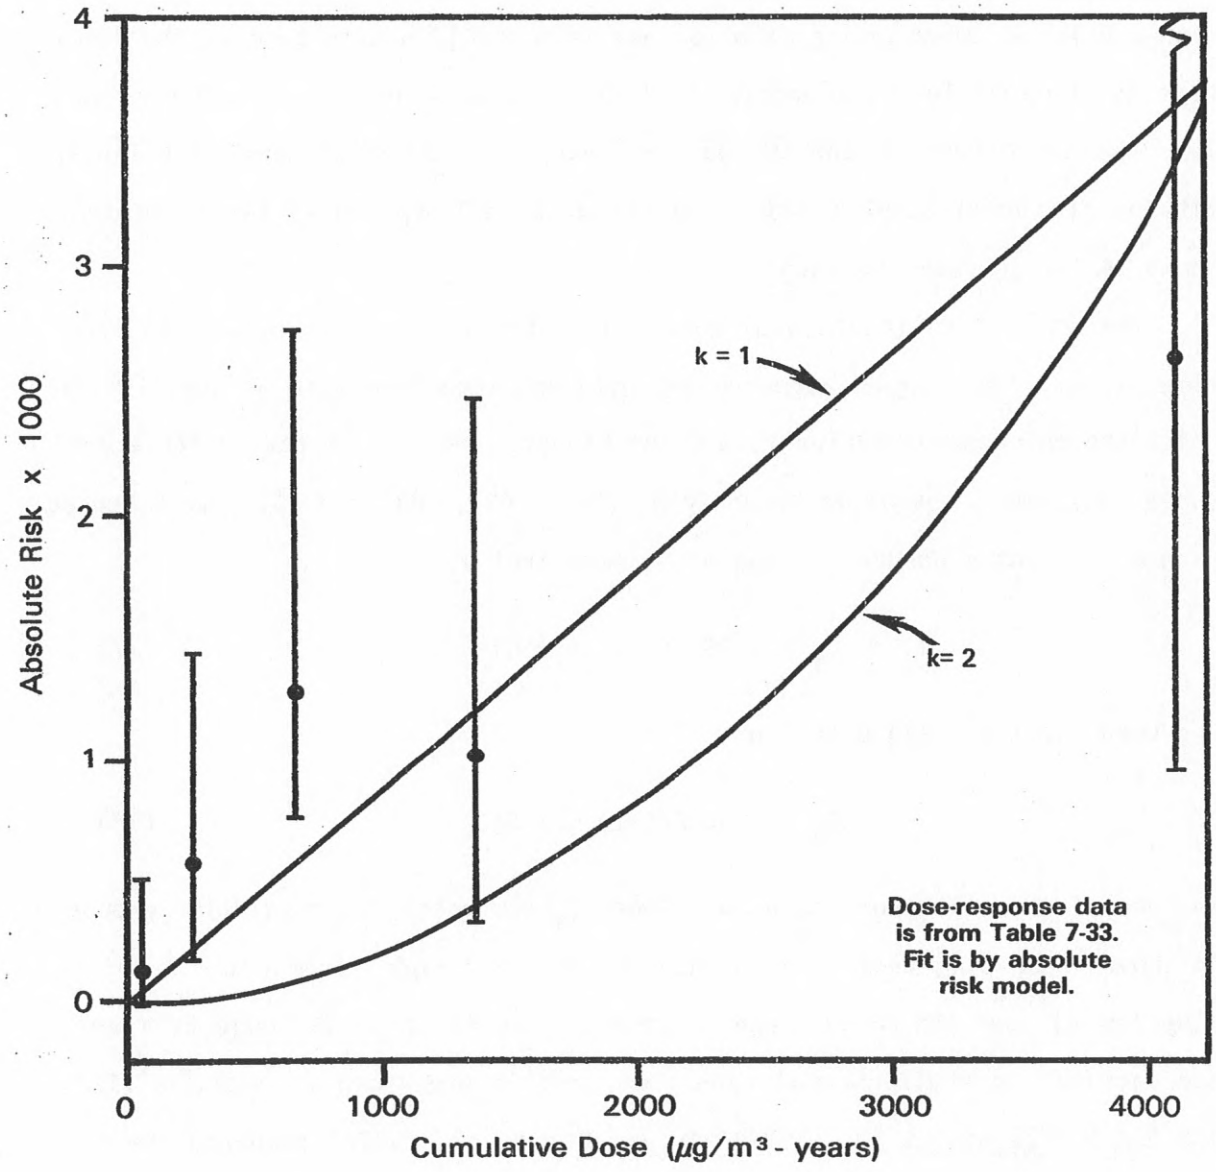

Figure 7-9. Absolute risks and 90% confidence limits for 10 year lag data of Enterline and Marsh (1982).

potency parameter a' are also listed in Table 7-25. The maximum-likelihood fits of these models are graphed in Figures 7-6 through 7-9. The quadratic fit (k = 2) is poor for both the absolute- and relative-risk models with either 0 lag or 10-year lag data (p less than 0.001 in each case). The linear fits to the relative-risk models are also relatively poor (p = 0.02 for the 0 lag data and 0.006 for the 10-year lag data). On the other hand, the linear fits of the absolute-risk model are all acceptable (p = 0.24 for 0 lag data and 0.14 for 10-year lag data).

The unit risks (additional risks of respiratory cancer death from lifetime exposure to 1 $\mu g/m^3$ airborne arsenic) obtained from each of the fits for which the chi-square p-value is 0.01 or higher, are also listed in Table 7-25. These risks were estimated by applying (1) or (2), (8), and (9) with D_i based upon a constant exposure of 1 $\mu g/m^3$. Specifically,

$$D_i = 4.56[5(i-1) + 2.5] \qquad (17)$$

was used for the 0 lag data, and

$$D_i = 4.56[5(i-1) - 7.5] \qquad (18)$$

was used for the 10-year lag data. These D_i represent the cumulative exposure in $\mu g/m^3$ resulting from a constant exposure to 1 $\mu g/m^3$ from birth to the midpoint of the ith 5-year age interval. The factor 4.56 converts from occupational to environmental exposures, and is explained at equation (11).

7.3.2.2.5 The Ott et al. (1974) study. Ott et al. (1974) compared the age-specific death patterns of 174 decedents exposed to arsenic in the production of pesticides to those of 1809 decedents who were not exposed to arsenicals. By fitting the death patterns of the unexposed decedents to a mathematical function, an estimate was obtained of the probability that a death at a parti-

cular age and during a particular epoch was due to respiratory cancer. This function was used to estimate expected respiratory cancer deaths in various exposure categories for the exposed decedents. Cumulative exposures were estimated for exposed decendents, using work histories and estimates of average exposures in various jobs. The exposure estimates were made by industrial hygienists familiar with the processes. Expected cancer deaths were compared with observed to obtain observed-to-expected ratios. Table 7-34 shows the results of Ott et al.'s dose-response analysis. The data in this table are all reproduced directly from Table 4 of Ott et al. (1974), except for the cumulative exposures. Average total exposures in mg provided by Ott et al. were converted to cumulative exposures in $\mu g/m^3$ years by multiplying by the factor

$$\frac{1000\ \mu g/mg}{(4\ m^3/day)(21\ days/mo)(12\ mo/year)} \qquad (19)$$

TABLE 7-34. DATA FROM TABLE 4 OF OTT ET AL. (1974)

Cumulative Exposure[a] $\mu g/m^3$-years	Observed Deaths	Expected Deaths
41.8	1	1.77
125	2	1.01
250	4	1.38
417	3	1.36
790	3	1.70
1544	2	0.97
3505	3	0.77
6451	5	0.79
29497	5	0.72

[a]Exposures are in $\mu g/m^3$-years estimated by:

$$\frac{d\ mg \times 1000\ \mu g/mg}{(4\ m^3/day)(21\ days/month)(12\ months/year)}$$

where d is average total exposure from Table 4 of Ott et al.

REC 5181

The values included in this factor are not in doubt because use of the factor simply negates the calculation of total exposure made by Ott et al.

Decedent studies such as this are more subject to bias then prospective studies such as those of Lee-Feldstein (1983) and Enterline and Marsh (1982). If, for example, in some age category arsenic exposure increased the mortality from some other disease in addition to respiratory cancer, an analyis of decedents might show an artificially low effect of arsenic upon respiratory cancer for this age group (because there might be an artificially large number of total deaths). It is also of some concern that Ott et al. did not clearly describe how the study cohort was defined.

This study involved primarily short-term exposures, as less than 25 percent of the decedents had worked with arsenicals for more than one year. Thus, this study is less appropriate for estimating risks from lifetime environmental exposure than a comparable study involving longer exposures. The study also was quite small; only 28 respiratory cancer deaths occurred among exposed decedents.

Development of risk estimates: The dose-response data in Table 7-34 were used in an assessment of risk. Because of the nature of the study, only a relative risk model could be applied to these data. The dose-response for relative risk is graphed in Figure 7-10. The response in the most highly exposed group falls far below that predicted by the lower-dose data and is omitted from Figure 7-10. This is possibly due to the fact that some of the more highly exposed workers wore respirators. Because of this shortfall in response, and also because the exposures to this group were the furthest from the low-level environmental exposures of interest, the data from the highest exposure group were omitted from the analysis.

Results of applying chi-square goodness-of-fit tests of the relative-risk model with $k = 1$ and $k = 2$ are listed in Table 7-25. The maximum-likelihood

REC 5182

TR 1867

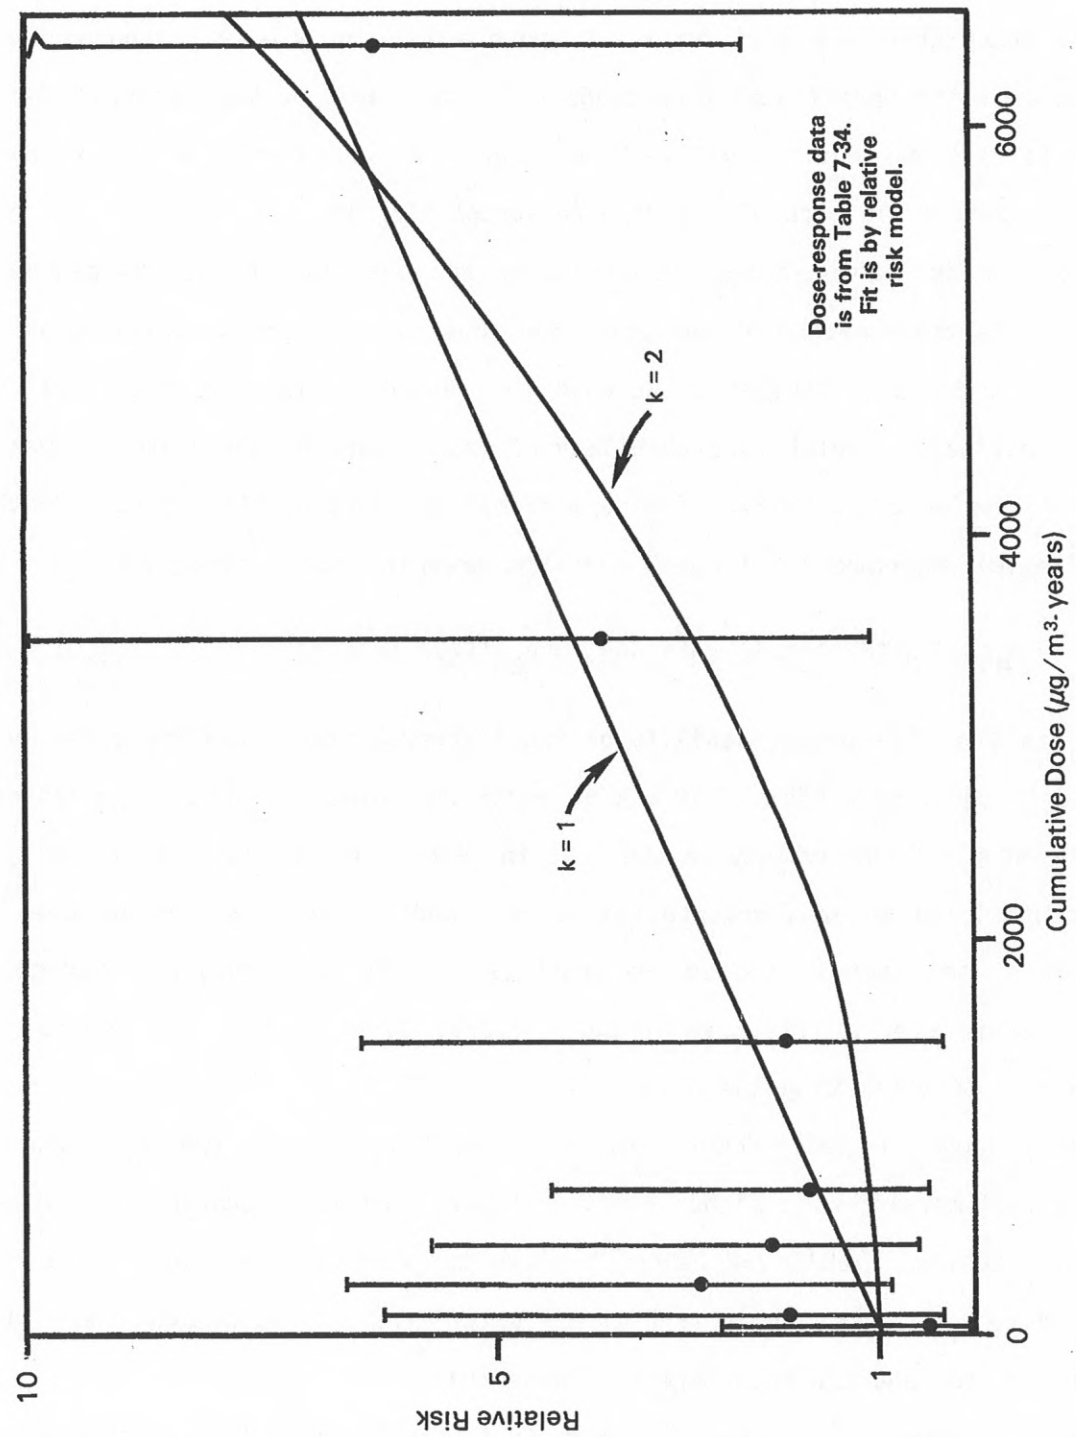

Figure 7-10. Relative risks and 90% confidence limits for data of Ott et al. (1974) with highest exposure group omitted.

estimates of the carcinogenic potency parameter a' are also listed in this table. The maximum-likelihood fits are graphed in Figure 7-10. Both of these fits are acceptable ($p = 0.66$ for $k = 1$ and $p = 0.23$ for $k = 2$), although the data appear to be more linear than quadratic. It should be kept in mind that the sample size was quite small in this study, and consequently a wide range of curve shapes would probably provide an acceptable fit.

The risk estimation method described in the previous section is based upon the life table method of analysis, and does not seem particularly appropriate for a decedent analysis. Because the method employed by Ott et al. seems to estimate a relative probability of respiratory cancer death, it was decided to estimate the extra lifetime probability of respiratory cancer death from lifetime exposure to d $\mu g/m^3$ airborne arsenic, using the expression

$$P_0(1 + a'[(72)(4.56)d]^k) - P_0 = P_0 a'[(72)(4.56)]^k. \qquad (20)$$

Here P_0 is the lifetime probability of respiratory cancer mortality given by (8), and is equal to 0.0451 if 1976 U.S. mortality rates are used. The factor 72 represents life expectancy in the U.S. in years. The factor 4.56 converts from occupational to environmental exposures, and is explained at equation (11). Thus, the term in the square brackets in (20) represents the average total exposure over a life span in $\mu g/m^3$ years, which is the same as the measure used in estimating the potency a'.

7.3.2.3 Discussion--Table 7-25 summarizes the fits of both absolute- and relative-risk models, with either $k = 1$ or $k = 2$, to dose-response data from 4 different studies. Table 7-25 also displays the carcinogenic potencies a'. It should be noted that the potencies estimated from different models are in different units, and are therefore not comparable.

In every case, a linear model ($k = 1$) fitted the data better than the corresponding quadratic model ($k = 2$). In every case but two, the fits of the

REC 5184

TR 1869

quadratic model could be rejected at the 0.01 level. The two exceptions involved the two smallest data sets (Higgins et al. absolute risk, and Ott et al.) and in the former case the fit was very marginal ($p = 0.017$). On the other hand, for each data set a linear model provided an adequate fit. Also, in every case, an absolute-risk linear model fit the data better than the corresponding relative-risk linear model. The p-values for the fits of the absolute-risk linear model ranged from 0.025 to 0.75.

The estimated unit risk is presented for each fit for which the chi-square goodness-of-fit p-value is greater than 0.01. The unit risks derived from linear models--8 in all--range from 0.0013 to 0.0136. The largest of these is from the Ott et al. study, which probably is the least reliable for developing quantitative estimates, and which also involved exposures to pentavalent arsenic, whereas the other studies involved trivalent arsenic. The unit risks derived from the linear ($k = 1$) absolute-risk models are considered to be the most reliable; although derived from 5 sets of data involving 4 sets of investigators and 2 distinct exposed populations, these estimates are quite consistent, ranging from 0.0013 to 0.0076.

To establish a single point estimate, the geometric mean for data sets is obtained within distinct exposed populations, and the final estimate is taken to be the geometric mean of those values. This process is illustrated in Table 7-35.

The final estimate is 4.29×10^{-3}, where exposure is in $\mu g/m^3$ of continuous exposure. Based upon an assumed 20 m^3 tidal volume of air and a 30 percent absorption rate, this amounts to a unit risk of $4.29 \times 10^{-3} \div (.3 \times 20 \times .001/70) = 50.1$ in units of mg/kg absorbed dose per day.

Although the estimates derived from the various studies are quite consistent, there are a number of uncertainties associated with them. The estimates

TABLE 7-35. COMBINED UNIT RISK ESTIMATES FOR ABSOLUTE-RISK LINEAR MODELS

Exposure Source	Study	Unit Risk	Geometric Mean Unit Risk	Final Estimated Unit Risk
Anaconda smelter	Brown & Chu	1.25×10^{-3}		
	Lee-Feldstein	2.80×10^{-3}	2.56×10^{-3}	
	Higgins	4.90×10^{-3}		4.29×10^{-3}
ASARCO smelter	Enterline & Marsh	6.81×10^{-3}		
		7.60×10^{-3}	7.19×10^{-3}	

were made from occupational studies that involved exposures only after employment age was reached. In estimating risks from environmental exposures throughout life, it was assumed, through either the relative-risk model (1) or the absolute-risk model (2), that the increase in the age-specific mortality rates of lung cancer was a function only of cumulative exposures, irrespective of how the exposure was accumulated. Although this assumption provides an adequate description of all of the data, it may be in error when applied to exposures that begin very early in life. Similarly, the linear models possibly are inaccurate at low exposures, even though they provide excellent descriptions of the experimental data.

The risk assessment methods employed were severely constrained by the fact that they were based only upon the analyses performed and reported by the original authors--analyses that had been performed for purposes other than quantitative risk assessment. For example, although other measures of exposure might be more appropriate, the analyses were necessarily based upon cumulative dose, since that was the only usable measure reported. Given greater access to the data from these studies, other dose measures, as well as models other than the simple relative-risk and absolute-risk models, could be

REC 5186

TR 1871

studied. It is possible that such wide analyses would indicate that other approaches are more appropriate than the ones applied here.

7.3.3 Unit Risk for Water

The best data available for making quantitative cancer risk estimates for ingestion of arsenic in water are the data collected by Tseng et al. (1968). They surveyed a stable population of 40,421 individuals who lived in a rural area along the southwest coast of Taiwan and who were known to have consumed drinking water containing arsenic. The occurrences of skin cancer among this population, and the arsenic concentrations in their drinking water, were measured. Since the population was stable, the study can be viewed as a lifetime feeding study, and the data may be used to predict the lifetime probability of skin cancer caused by the ingestion of arsenic.

A model estimating the cancer rate as a function of drinking water arsenic concentration was generated using information from the above study in its published form, which is a summary of data collected by the investigators. If the original data had been available, a more exact mathematical analysis would have been possible.

Doll (1971) has suggested that the relationship between the incidence of some site-specific cancers, age, and exposure level of a population may be expressed as:

$$I(x,t) = kBx^m t^{k-1} \qquad (21)$$

where x is the exposure level (which can be measured by the water concentration in ppm), t is the age of the population, and B, m, k are unknown parameters.

However, the data collected by Tseng et al. (1968) was obtained at one point in time, and since skin cancer has only a marginal effect on the death

rate, the obtained rates may be viewed more accurately as the probability of having contracted skin cancer by time t. The relationship between this probability, often referred to as the cumulative probability density or prevalence F(x,t), and the incidence or age-specific or hazard rate, may be expressed as:

$$F(x,t) = 1 - \exp\left[-\int_0^t I(x,s)\, ds\right]. \qquad (22)$$

Utilizing equation (21) as the form of the incidence rate, the prevalence may be expressed as

$$F(x,t) = 1 - \exp\left(-Bx^m t^k\right), \qquad (23)$$

which is a Weibull distribution.

In Table 7-36, adapted from information in Tseng, et al. (1968), estimates are given of F(x,t) for different age and water concentration groupings for males. The prevalence for females is less than for males, and therefore is not used to estimate risk.

To use this data, specific values for x and t had to be obtained for the intervals. Where the intervals were closed, the midpoint was utilized. For the greater than 0.6 ppm group, the midpoint between 0.6 and the greatest recorded value, 1.8, was taken, resulting in 1.2 ppm. For age 60 or greater, a value of 70 was utilized somewhat arbitrarily, being the same increase over the lower level as that in the other two age intervals. The values for (x,t) to relate to the prevalence estimates are shown in parentheses in Table 7-36.

From equation (23) it follows that

$$\ln(-\ln[1-F(x,t)]) = \ln(B) + m\ln(x) + k\ln(t), \qquad (24)$$

which is multiple-linear in form. Estimating the parameters by the usual least-square techniques, the following relationship is obtained:

TABLE 7-36. AGE-EXPOSURE-SPECIFIC PREVALENCE RATES FOR SKIN CANCER

Exposure in ppm[3]	AGE 20-39 (30)	AGE 40-59 (50)	AGE ≥60 (70)
0 - 0.29 (0.15)	0.0013	0.0065	0.0481
0.30 - 0.59 (0.450)	0.0043	0.0477	0.1634
≥0.6 (1.2)	0.0224	0.0983	0.2553

*Source: Tseng et al. (1968).

[a]Range given by authors. Midpoint is in parentheses.

$$\ln(- \ln[1 - F(x,t)]) = 17.548 + 1.192 \ln(x) + 3.881 \ln(t), \quad (25)$$

which is an excellent fit, having a multiple correlation coefficient of 0.986 and a standard error on the exposure regression m of .138.

Equation (25) may be expressed as

$$F(x,t) = 1\text{-}\exp\text{-}[2.429 \times 10^{-8}(X^{1.192})(t^{3.881})]$$
$$= 1\text{-}\exp\text{-}[X^{1.192}\ H(t)] \quad (26)$$

If the parameter m = 1.192 were in fact equal to 1, then for a given value of t, equation (26) would be "one-hit" in form.

To test this hypothesis (i.e., Ho: m = 1) the student "t" test is used, giving the result:

$$t_6 = \frac{1.192 - 1}{0.138} = 1.391,$$

which is not significant at the 0.1 level. Thus, there is insufficient evidence to reject the hypothesis that the dose-response relationship is "one-hit" even at the 0.1 level. However, a quadratic model would be rejected at the $p<.001$ level.

Fixing m = 1, the following relationship is obtained:

$$F(x,t) = 1 - \exp[-g(t)x] \qquad (27)$$

Transforming this equation to its linear form (as in equation 23) and obtaining the least-square linear estimates of B and v, it is found that:

$$g(t) = \exp(-17.5393)\, t^{3.853}, \text{ where } B = 2.41423 \times 10^{-8}, \; k = 3.853.$$

The data used to obtain these estimates are shown in Table 7-37, and the goodness-of-fit is illustrated in Figure 7-11.

	70	0.2553	0.3110	1.22155	0.98751

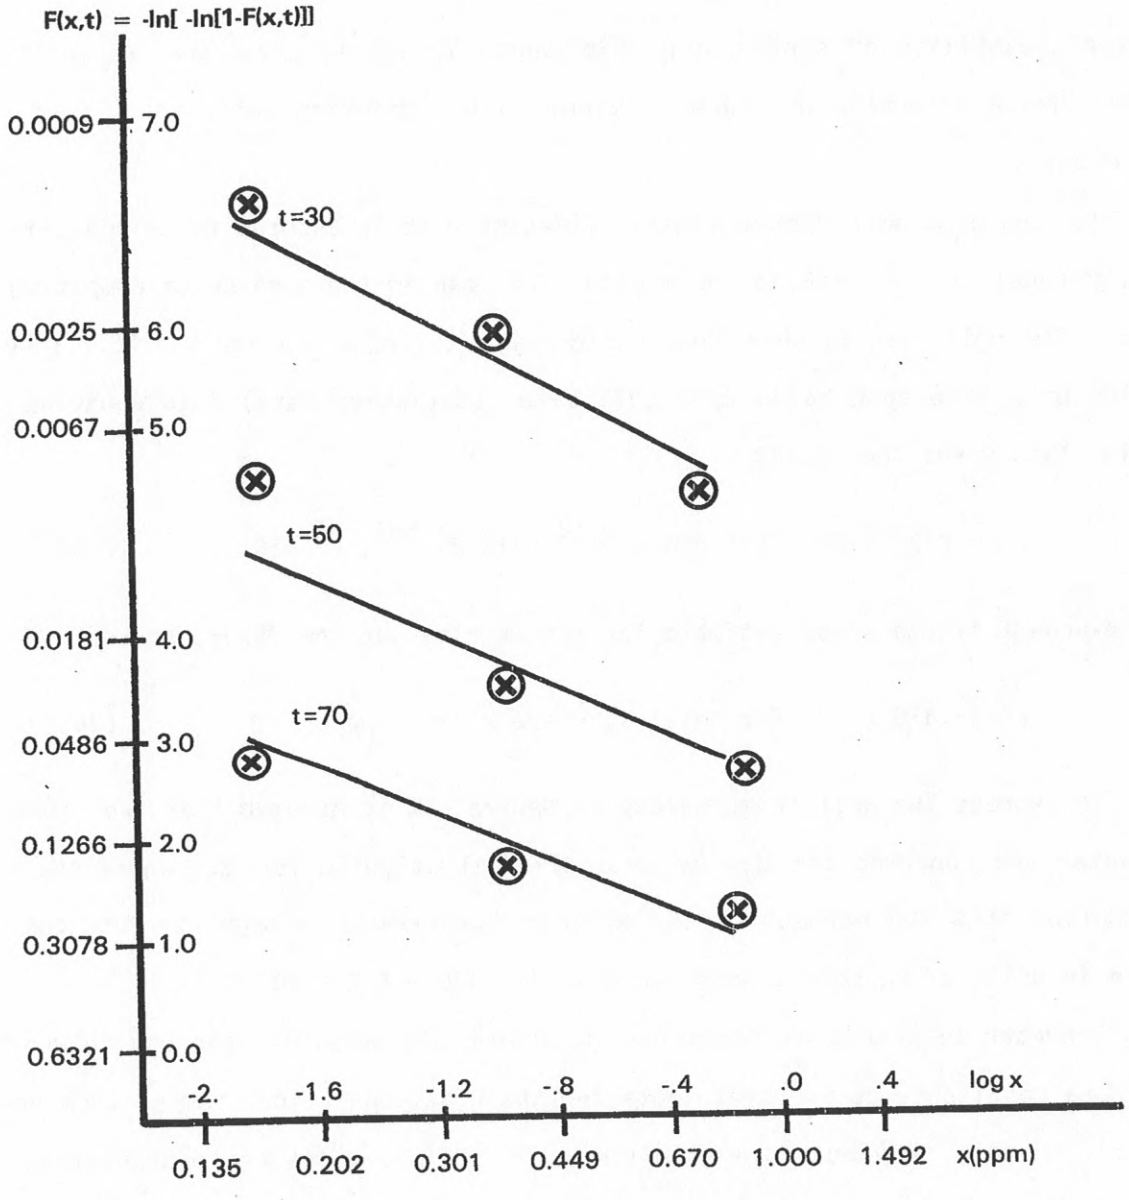

Figure 7-11. Relationship between transformed prevalence and log ppm arsenic in water, log age.

The function

$$F(x,t) = 1-\exp[-2.41423 \times 10^{-8} \times t^{3.853}], \qquad (28)$$

is the probability of contracting skin cancer by age t, given that an individual had a life-time exposure to x ppm in his drinking water (and lived until age t).

To obtain a unit risk estimate, lifetime risk is assumed to be approximately equal to the risk to the median life span in the absence of competing risk. The unit risk is thus obtained by substituting x = 1 and t = 76.2 (the median U.S. life span based upon 1976 vital statistics data) into equation (28). This gives the result

$$P(1) \tilde{=} 1-\exp[-2.414 \times 10^{-8} \times 76.2^{3.853}] = .350 \qquad (29)$$

The exponent is the slope estimate for cancer risks at low doses, so that:

$$P(x) \tilde{=} .430\ x \qquad \text{for small } x, \text{ where } x \text{ is in ppm.} \qquad (30)$$

To express the unit in mg/kg/day exposures, it is assumed that two liters of water are consumed per day by an individual weighing 70 kg. Under the assumption that 100 percent of the arsenic is absorbed through the gut, the slope in units of mg/kg/day absorbed dose is $.430 \div (.2 \div 70) = 15.8$.

A number of potential factors exist that could possibly make the Taiwanese data unsuitable as surrogate data for the U.S. population. Among them are racial, dietary, and nutritional differences. Also, exposure to ergotamine was confounded with arsenic exposure in the well water--a fact which also could have modified the results. However, there is no direct evidence demonstrating the role of these agents in the carcinogenic response to ingested arsenic. Furthermore, a recent extensive review by Andelman and Barnett (1983)

REC 5192

TR 1877

of the arsenic dose-response model developed here, demonstrates that presently there is no quantitative evidence that is inconsistent with the model. The Andelman and Barnett study also showed that there does not appear to be any population in the U.S. that could be studied that would have a reasonable power to contradict the hypothesis that the Taiwanese dose-response model is consistent with the U.S. dose response.

7.3.4 Relative Potency

One of the uses of the concept of unit risk is to compare the relative potencies of carcinogens. To estimate relative potency on a per-mole basis, the unit risk slope factor is multiplied by the molecular weight, and the resulting number is expressed in terms of $(mMol/kg/day)^{-1}$. This is called the relative potency index.

Figure 7-12 is a histogram representing the frequency distribution of potency indices of 52 chemicals evaluated by the CAG as suspect carcinogens. The actual data summarized by the histogram are presented in Table 7-38. Where human data were available for a compound, they were used to calculate the index. Where no human data were available, animal oral studies and animal inhalation studies were used, in that order. Animal oral studies were selected over animal inhalation studies because they have been made on most of the chemicals, thus allowing potency comparisons by route.

The potency index for arsenic, based on the Tseng et al. study, is 2.25×10^3 $(mMol/kg/day)^{-1}$. This is derived by means of the slope estimate from the Tseng et al. study, which is $15(mg/kg/day)^{-1}$.

Multiplication by the molecular weight of 149.8 gives a potency index of $2.25 \times 10^{+3}$. Rounding off to the nearest order of magnitude gives a value of 10^{+3}, which is the scale presented on the horizontal axis of Figure 7-12. The index of $2.25 \times 10^{+3}$ lies at the bottom of the first quartile of the 52 suspect carcinogens.

Remarks:

1. Animal slopes are 95% upperlimit slopes based on the linear multistage model. They are calculated based on animal oral studies, except for those indicated by I (animal inhalation), W (human occupational exposure), and H (human drinking water exposure). Human slopes are point estimate, based on the linear non-threshold model.

2. The potency index is a rounded-off slope in (mMol/kg/day)-1 and is calculated by multiplying the slopes in (mg/kg/day)-1 by the molecular weight of the compound.

3. Not all the carcinogenic potencies presented in this table represent the same degree of certainty. All are subject to change as new evidence becomes available.

Ranking of the relative potency indices is subject to the uncertainty involved in comparing estimates of potency for different chemicals based on different routes of exposure to different species, and using studies of different quality. Furthermore, all the indices are based on estimates of low-dose risk using linear extrapolation from the observational range. Thus, these indices are not valid for the purpose of comparing potencies in the experimental or observational range if linearity does not exist there.

7.3.5 Summary and Conclusions of the Carcinogenicity of Arsenic

7.3.5.1 Qualitative Summary--Human studies of the effects of arsenic from smelters, drinking water, pesticide manufacturing plants, and medicinals have

REC 5197

been conducted. These are summarized in Table 7-1. Studies of five independent smelter worker populations have all found an association between occupational arsenic exposure and lung cancer mortality. Several of the smelter studies have found a dose response both by intensity and by duration of exposure. The risk of lung cancer mortality in the high dose group of one study of smelter workers in Japan was found to be 10 times that expected. Some of the recent data from these smelter studies suggest that, if the multistage theory of carcinogenesis is correct, arsenic may act as a late-stage carcinogen. It is also possible to hypothesize from some of the data that arsenic may be a promoter. Either of these hypotheses, however, requires further study. In addition, some studies of communities surrounding smelters have found an association between geographic proximity to the smelter and lung cancer mortality.

Both proportionate mortality and cohort studies of pesticide manufacturing workers have demonstrated an excess of lung cancer deaths among workers in that occupation. One study of the population around a pesticide manufacturing plant found that residents of the area surrounding the plant were also at an excess risk of lung cancer. Several case reports of arsenical pesticide applicators have also shown an association between arsenical exposure and lung cancer.

A study of 40,000 persons in Taiwan exposed to arsenic in the drinking water found a significant excess prevalence of skin cancer over that of 7,500 other Taiwanese and residents of Matsu Island who drank water relatively free of arsenic. Water supplies in Chile and Argentina were also reported to be the cause of arsenic-induced skin cancers. In contrast, studies of populations in the United States exposed to relatively high levels of arsenic in the drinking water by U.S. standards did not find any excess of skin cancer.

The difference in response between the Taiwanese and the United States studies may reflect the fact that the drinking water in the study area in Taiwan

REC 5198

TR 1883

contained much higher levels of arsenic than did the drinking water in the United States. Furthermore, the Taiwanese waters also contained ergotamine-like compounds. Other differences between the two study areas include differences in socioeconomic status, with the Taiwanese who developed skin cancer belonging to a rather low socioeconomic strata which could have had ramifications in terms of diet, personal hygiene and medical care. Racial differences may have also contributed to the differences between the study results. In addition to these physical and cultural differences, the U.S. studies were limited by small sample sizes and would not have detected the risk from skin cancer that would have been predicted, on the basis of arsenic ingestion, from a linear model of the Taiwanese data.

Persons exposed to arsenical medicinals have also been shown to be at a risk of skin cancer.

Using the International Agency for Research on Cancer (IARC) classification scheme for evaluating carcinogens, the evidence for arsenic as a human carcinogen is considered sufficient. This is evidenced by the high relative risks, the consistency in findings in different studies, and the specificity of tumor sites (i.e., skin and lungs).

Consistent demonstration of arsenic carcinogenicity in test animals, using different chemical forms, routes of exposure, and various experimental species, has not been observed. Nevertheless, recent data indicate that tumorigenicity and possibly carcinogenicity can be demonstrated in animals if the retention of arsenic in the lung is increased. The additional observation that calcium arsenate is only slowly cleared from the lung, strongly suggests that this agent may be carcinogenic. In support of the recent animal studies, is the observation that cultured Syrian hamster embryo cells can be transformed by direct exposure to sodium arsenate.

7.3.5.2 Quantitative summary--Unit risks are estimated for both air and water exposures to arsenic. The air estimates were based on data obtained in five separate studies involving three independently exposed worker populations. Linear and quadratic dose-response models in both the absolute and relative form are fitted to the worker data. It was found that for the models that fit the data at the P = .01 or better level that the corresponding unit risk estimates ranged from 1.05×10^{-4} to 1.36×10^{-2}. However, linear models fit better than quadratic models and absolute better than relative models. Also it was felt that exposure to trivalent arsenic was more representive of low environmental exposure than pentavalent arsenic. Restricting unit risk estimates to those obtained from linear absolute models where exposure was to trivalent arsenic gives a range of 1.25×10^{-3} to 7.6×10^{-3}. A weighted average of the five estimates in this range gave a composite estimate of 4.29×10^{-3}.

An extensive drinking water study of the association between arsenic in well water and an examination for skin cancer of a population who lived in a rural area of Taiwan was used to estimate the unit risk for ingestion. Using the male population who appeared to be more susceptible, it was estimated that the unit risk associated with drinking water contaminated with 1 μg/ℓ of arsenic was 4.3×10^{-4}. To compare the air and water unit risks, the exposure units in both cases were converted to mg/kg/day absorbed doses, resulting in unit risk estimates of 50.1 and 15.0, respectively.

The potency of arsenic compared to other carcinogens is evaluated by noting that an arsenic potency of $2.25 \times 10^{+3}$ $(\text{mMol/kg/day})^{-1}$ lies in the first quartile of the 52 suspect carcinogens that have been evaluated by CAG.

7.3.5.3 Conclusions--Skin cancer and lung cancer have been shown by numerous epidemiologic studies to have an association with arsenic exposure. Arsenic

has not definitively been found to be a carcinogen in animal studies, however. In applying the IARC criteria for evaluating a substance as to the weight of evidence for human carcinogenicity, arsenic would be placed in group 1, which IARC characterizes as "carcinogenic to humans."

Using the linear absolute risk model, the composite estimate for cancer risk due to a lifetime exposure to 1 $\mu g/m^3$ trivalent arsenic in the air is estimated to be 4.29×10^{-3}. The unit risk due to lifetime exposure to 1 $\mu g/\ell$ of arsenic in drinking water is estimated to be 4.3×10^{-4}. On the basis of mg/kg/day absorbed dose, the unit-risk slope estimates for air and water are 50.1 and 15, respectively. While it is unlikely that the true risks would be higher than these estimates, they could be substantially lower. Compared to other compounds on a mole unit basis, the carcinogenic potency for arsenic falls towards the lower end of the first quartile.

8. ARSENIC AS AN ESSENTIAL ELEMENT

Mertz (1970) has set forth a set of logical criteria which trace elements should obey in order to be considered physiologically essential for man and/or animals. One of the most obvious of these, and one which should be readily demonstrable, is that the element meet a unique requirement physiologically, and, consequently, that a deficiency in that element be associated with deleterious effects.

In the case of arsenic, early reports attempting to show a nutritional requirement for the element in animals were inconclusive (Arsenic. NAS, 1977; Underwood, 1977). Part of the problem was undoubtedly technical in nature, i.e., the difficulty of carrying out such studies in an experimental environment where rigorous exclusion of a ubiquitous element from the diet is necessary. More recently, however, several carefully controlled studies have been reported to have demonstrated nutritional essentiality for arsenic in at least some mammalian species.

Nielsen et al. (1978) have noted that deprivation of pregnant rats of arsenic-supplemented diets resulted in offspring showing such post-weaning effects as slow growth, enlarged spleens, and increased red cell osmotic fragility. Greater perinatal mortality among pups from arsenic-deprived dams was also noted in a second experimental group.

In a recent review by Uthus et al. (1983), the authors reported on studies with chicks that suggest that arsenic influences arginine metabolism. It was reported that arsenic deprivation influenced the effects of dietary arginine, manganese and zinc, the fluctuations of which variously affected growth, kidney arginase, plasma alkaline phosphatase, plasma urea, plasma uric acid

and hematocrit. The authors suggested that the four components interacted to affect the conversion of arginine into urea and ornithine.

Anke et al. (1978) studied the nutritional requirements for arsenic using goats and mini-pigs and a semi-synthetic diet containing less that 50 ppb arsenic. Effects attributed to arsenic deficiency in both species were seen not only in the adult animals but in their offspring. Arsenic deficiency increased the mortality of adult goats as well as altered the mineral profiles for copper and manganese in the carcass. Significant reproductive effects for both arsenic-deficient goats and mini-pigs included reduction of the normal litter size. Furthermore, the mortality of kids and piglets from the arsenic-deficient groups was significantly higher than controls. Manganese levels were elevated in arsenic-deficient kids and piglets, but no perturbation of hematological indices (hemoglobin, hematocrit or mean corpuscular concentration) was noted. This is in contrast to the experimental observations with rats (Nielsen et al., 1974), where decreased hematocrits, elevated iron content in spleen and increased osmotic fragility of cells are seen. Given the fact that the rat is known to be an anomalous animal model for arsenic metabolism (see Chapter 4), this difference is probably peculiar to this species.

Schwartz (1977) has noted growth effects of arsenite on rats fed an arsenic-supplemented diet, with an optimal effect seen at 0.25 to 0.5 ppm. Interestingly, this worker noted that pentavalent arsenic as sodium arsenate is less effective.

Remaining to be independently demonstrated is a physiological role for arsenic, the existence of any specific carrier agent in the body, or arsenic essentiality in man.

A feature of essential element metabolism is homeostatic control of levels and movement of a particular element *in vivo*. From the information

considered earlier, there is no effective absorption barrier for most soluble inorganic arsenicals, but efficient excretory mechanisms (kidney, hair) and biotransformation appear to provide some control over any absorption-excretion balance.

9. HUMAN HEALTH RISK ASSESSMENT FOR ARSENIC

This portion of the report places the information in the earlier Chapters into a quantitative perspective with regard to non-occupational population exposure and health effects of arsenic germane to such a population.

Data for levels of arsenic encountered by humans in air, water, food and other sources, such as cigarette smoking, were set forth in Chapter 3 and are combined with data on rates of intake and rates of absorption to provide information on the total assimilation of arsenic on a daily basis. Health effects of arsenic most germane to non-occupational population exposures are then summarized. Generally, these are chronic effects associated with long-term intake of relatively low levels of arsenic. In the case of hazardous wastes, however, some health effects of concern may be associated with acute exposures; therefore, acute and sub-acute effects must also be considered.

The section dealing with dose-effect/dose-response data includes consideration of various indices of internal exposure followed by quantitative data for intake and population response.

Populations at risk, identified at least along qualitative lines, are included for discussion.

9.1 AGGREGATE EXPOSURE LEVELS TO ARSENIC IN THE U.S. POPULATION

Among individuals of the general population (not occupationally exposed to arsenic), the main routes of exposure to arsenic are typically via ingestion of food and water, with lesser exposures occurring via inhalation. Representative intake figures are presented in Table 9-1. Intake by inhalation is augmented among smokers in proportion to the level of smoking.

REC 5207

TABLE 9-1. ROUTES OF DAILY HUMAN ARSENIC INTAKE

Route/level	Rate	Total intake	Absorbed amount
Ambient air/0.006 μg/m^3[(a)]	20 m^3	0.12 μg	0.036 μg[(b)]
Drinking water/≤ 10 μg/liter	2 liters	≤ 20 μg	≤ 20 μg[(c)]
Food/50 μg daily (elemental As)	--	50 μg	40 μg[(d)]
Cigarettes/6 μg in mainstream smoke/pack[(e)]	1/2 pack	3 μg	0.9 μg[(f)]
	1 pack	6 μg	1.8 μg[(f)]
	2 pack	12 μg	2.7 μg[(f)]
Total: ≤ 60 μg nonsmokers			

(a) National average for 1981 (see Section 3.3.1)
(b) Assumes 30 percent respiratory absorption (see Chapter 4).
(c) Assumes total absorption (see Chapter 4).
(d) Assumes 80 percent absorption (see Chapter 4).
(e) Assumes 20 percent of cigarette content in inhaled smoke (see Chapter 4).
(f) Assumes 30 percent absorption of inhaled amount (see Chapter 4).

Assuming a daily ventilation rate of 20 m^3, and a national population inhalation average of 0.006 μg/m^3/As, the total daily inhalation exposure for arsenic can be projected to be approximately 0.12 μg. Assuming 30 percent absorption, approximately 0.03 μg of arsenic would be absorbed on a daily average.

Contribution of tobacco-borne arsenic to the respiratory burden would depend upon the rate of cigarette smoking. If one assumes a mass of 1 gram/cigarette and an average tobacco value of 1.5 ppm, this yields 1.5 μg arsenic/cigarette. With 20 percent of this amount in mainstream smoke, the inhaled amount for each pack of cigarettes would be approximately 6 μg arsenic, and of this amount, 40 percent would be deposited in the respiratory tract (see Chapter 4). Assuming an absorption of 75 percent of the deposited fraction, one arrives at an absorption of approximately 2 μg/pack of cigarettes or a

factor of 10 to 100 times greater than intake for nonsmokers in given ambient air settings. One may assume that the rates of absorption for trivalent and pentavalent arsenic in the respiratory tract are equivalent.

Since drinking water arsenic is mainly in a soluble form (arsenate or arsenite), virtually all of it is absorbed in the GI tract (see Chapter 4). Thus, assuming an average daily consumption of two liters of water containing at most 10 µg As/liter as an outside high figure, one can estimate that the total arsenic absorbed from drinking water would be approximately 20 µg/day. Most individuals would, in reality, take in much less than this amount, while those in the Western U.S. with well water supplies much higher in arsenic content would assimilate proportionately more.

Food arsenic values taken from the 1974 FDA survey indicate a daily total dietary intake of approximately 50 µg elemental arsenic. Based on information presented in Chapter 4, the major portion (80 percent) of food arsenic would be absorbed resulting in a net daily food arsenic absorption of 40 µg total.

Thus, a non-smoker would have a total daily absorption from all exposure media of approximately 60 µg arsenic/day or less. Of this, the diet would be the major contributor, assuming levels in water much below 10 µg/liter. For cigarette smokers, one would add 2 µg arsenic/pack of cigarettes smoked daily.

If one views aggregate intake not in terms of total arsenic intake but in terms of toxicologically significant forms of the element, then much of the dietary fraction, for reasons given earlier, such as complex organoarsenicals being present, becomes relatively less important than the forms in water and air as well as in cigarette smoke. Arsenic forms in such media include: pentavalent arsenic in most water supplies; variable mixtures of tri-and pentavalent arsenic in ambient air; and probably an arsenic oxide in cigarette smoke. From this view point, utilizing the examples already given above, non-

smokers would absorb 20 μg or less daily of toxicologically significant arsenic. Heavy smokers having otherwise very low air and water exposure, conceivably could receive their major exposure via cigarettes.

9.2 SIGNIFICANT HUMAN HEALTH EFFECTS ASSOCIATED WITH AMBIENT EXPOSURES

9.2.1 Acute Exposure Effects

Serious acute effects and late sequelae from exposure to arsenic will appear after single or short-term respiratory or oral exposures to large amounts of arsenic. Available data indicate that inorganic trivalent compounds of arsenic are generally more acutely toxic than inorganic pentavalent compounds, which in turn are more toxic than organic arsenic compounds. Serious effects will also appear after long-term exposure to respiratory or oral doses of arsenic.

The acute symptoms following oral exposure consist of gastrointestinal disturbances, which may be so severe that secondary cardiovascular effects and shock may result and cause death. Also, direct toxic effects on the liver, blood-forming organs, the central and peripheral nervous systems, and the cardiovascular system may appear. Some symptoms, especially those from the nervous system, may appear a long time after exposure has ceased and may not be reversible, whereas the other effects seem to be reversible. Infants and young children especially are susceptible with regard to effects on the central nervous system. The Japanese follow-up after the Morinaga milk poisoning showed that persisting damage, especially mental retardation and epilepsy, is a late sequela in children of short-term oral exposure to large doses of inorganic arsenic. Among adults, the central nervous system is not as susceptible, but peripheral neuropathy has been a common finding.

Both in adults and children, acute oral exposure has resulted in dermal changes, especially hyperpigmentation and keratosis, as a late sequela.

Acute inhalation exposures have also resulted in irritation of the upper respiratory tract, even leading to nasal perforations.

Direct dermal exposure to arsenic may lead to dermal changes; allergic reactions may also be involved.

9.2.2 Chronic Exposure Effects

Both carcinogenic and non-carcinogenic effects are associated with long-term exposures, which do not cause any obvious immediate effects. For the purpose of this document, such chronic effects will be discussed in sequence as follows:

1. Respiratory tract cancer
2. Skin cancer
3. Non-cancerous skin lesions
4. Peripheral neuropathological effects
5. Cardiovascular changes

Cancer of the respiratory system is clearly associated with exposure to arsenic via inhalation. This association has been especially noted among workers engaged in the production and usage of pesticides and among smelter workers. While it is not known to what extent exposure to other compounds in industrial atmospheres has contributed to the excess of lung cancer, the Carcinogen Assessment Group (CAG) has concluded that there is sufficient evidence that inorganic arsenic compounds are lung carcinogens in humans.

Cancer of the skin has been found as a dose-related effect in a population in Taiwan, with lifetime exposure to arsenic in well water. It has also been found among people treated with large doses of arsenite for skin disorders. Skin cancer often has a long latency period on the order of decades, the latency time decreasing with increasing intensity of exposure. The CAG has concluded that there is sufficient evidence that inorganic arsenic compounds are skin carcinogens in humans.

Hyperkeratosis and hyperpigmentation, sometimes with precancerous changes, have been a common finding in persons ingesting arsenic. These skin lesions, as well as the manifest cancer, develop on skin surfaces usually unexposed to sunlight. In studies in the United States, an association between skin lesions or skin cancer has not been demonstrated. These studies have been limited, however, by sample sizes too small to be able to detect the dose response seen in studies outside the U.S.

The effects on the peripheral nervous system range from sensory disturbances to motor weakness and even paralysis. The more severe signs have been noted in subacute poisonings, but more subtle changes after long-term low-level exposure have been found by using electromyography or measuring nerve conduction velocity. These subclinical effects are slow in recovery and may persist for years after cessation of exposure. In a study in Canada, electromyographic (EMG) changes were noted when water concentrations of arsenic exceeded 0.05 mg/l.

Cardiovascular effects have been noted especially in Taiwan, where Blackfoot disease (peripheral vasculopathy) occurred after long-term exposure to arsenic in well water. However, the presence of ergotamine-like compounds raises the possibility of vascular effects from these agents. Peripheral vascular changes were also found among German vintners who were exposed both occupationally, by spraying arsenic-containing pesticides, and orally, by drinking wine with elevated arsenic levels. Studies on occupationally-exposed persons have been inconclusive in showing that arsenic causes an increase in mortality from cardiac disease.

9.3 DOSE-EFFECT/DOSE-RESPONSE RELATIONSHIPS

9.3.1 General Considerations

This section generally attempts to define, as presently feasible, human dose-effect/dose-response relationships for health effects of likely greatest

concern at ambient environment exposure levels for arsenic in the United States. As such, the present section highlights mainly the quantitative carcinogenic risk estimates that were derived in Section 7.3.

The general question of how to define and employ a dose factor in attempts at quantitative assessments of human health risk for any toxicant is highly dependent upon: 1) the available information on the body's ability to metabolize the agent, and 2) the assessment of the relative utility of various internal indices of exposure.

The time period over which a given total intake occurs is highly important. For example, intake of one gram of arsenic over a period of years would be quite different pathophysiologically from assimilating this amount at one time, the latter probably having a lethal outcome. This time-dependent behavior is related in part to the relative ability of the body to detoxify inorganic arsenic by methylation as a function of both dose and time.

In cases of acute and sub-acute exposure, indicators of internal exposure such as blood or urine arsenic levels are probably appropriate for assessing the intensity of exposure.

With chronic, low-level exposure, however, the available data would indicate that the total amount assimilated is probably more important than an indicator concentration without knowledge of the total exposure period. An added problem is the background level of arsenic found in these indicators due to dietary habits. For example, in acute exposures, levels in blood or urine would be greatly elevated over background values while low-level chronic exposures would only result in moderate increases over background.

In regard to hair arsenic levels as an indicator of internal arsenic exposure, no reliable methods exist for distinguishing external contamination levels from those accumulated via absorption and metabolic distribution. Hair arsenic levels cannot, therefore, be employed as reliable indicators of either

current or cumulative long-term exposures for individual subjects, but rather may provide only a rough overall indication of group exposure situations.

Given the above considerations and limitations concerning the use of blood, urinary or hair arsenic concentrations as internal indices of cumulative, long-term low-level arsenic exposures of concern here, the dose-effect/dose-response relationships summarized below are done so mainly in terms of external arsenic exposure levels via either inhalation or ingestion.

9.3.2 Effects and Dose-Response Relationships

It is difficult to define a precise acute lethal dose of arsenic for man, because such exposure situations rarely allow accurate determination of the effective amounts. However, for trivalent arsenic, the figure is believed to range from 70 - 180 milligrams.

For subacute exposure, it appears that for children, about one gram assimilated over a period of 3-4 weeks will induce death with severe effects in survivors, while for adults, that dose will occasion significant clinical effects. In one poisoning episode, intake of approximately 50 milligrams over a period as short as two weeks resulted in clinically demonstrable effects in adults.

9.3.2.1 Respiratory Cancer--A considerable number of studies have shown associations between occupational exposure to arsenic and cancer of the respiratory system. The best information available for making quantitative risk estimates for lung cancer are derived from 5 sets of data involving 4 sets of investigators and 2 distinct exposed populations. The 4 sets of investigators are Brown and Chu (1983a,b,c), Lee-Feldstein (1983) and Higgins (1982)--who conducted studies on workers at the Anaconda smelter in Montana--and Enterline and Marsh (1982)--who conducted a study on the workers at the ASARCO smelter in Tacoma, Washington.

REC 5214

TR 1899

Using an absolute-risk linear model and the data from the four smelter studies, the lifetime lung cancer risk, due to continuous exposure of 1 μg/As/m^3, was estimated to range from 1.25×10^{-3} to 7.6×10^{-3}. A weighted average of the five estimates* in this range gave a composite estimate of 4.29×10^{-3} (see Section 7.3.2.3). This represents a plausible estimate of the upper limit of risk--that is, the true risk would not likely be more than the estimated risk, but it could be substantially lower.

9.3.2.2 Skin Cancer--Chronic arsenic exposure, both occupational and non-occupational, is associated with a distinctive hyperkeratosis, which is usually followed by a later onset of skin cancer. The best data available for making quantitative risk estimates for skin cancer are the data collected by Tseng et al. (1968). In this study, the authors surveyed a stable population of 40,421 individuals who lived in a rural area along the southwest coast of Taiwan and who were known to have consumed drinking water containing arsenic. The occurrences of skin cancer among this population and the arsenic concentrations in their drinking water were measured. Since the population was stable, the data obtained from the study lends itself to predictions of lifetime probability of skin cancer caused by the ingestion of arsenic.

Using an absolute-risk linear model and the data from Tseng et al., the lifetime skin cancer risk from drinking water containing 1 μg/liter of arsenic was estimated to be 4.3×10^{-4} (see Section 7.3.3). It is not likely that the true risk for skin cancer would be more than this estimated risk, but it could be considerably lower.

9.3.2.3 Non-cancerous Skin Lesions -- As noted above, in man, chronic oral exposure to arsenic induces a sequence of changes in skin epithelium, proceeding from hyperpigmentation to hyperkeratosis, characterized as keratin proliferation

---

*Two risk estimates were derived from the Enterline and Marsh study based upon exposure periods lagged 0 and 10 years. See Table 7-25.

REC 5215

TR 1900

of a verrucose nature and leading, in some cases, to late onset skin cancers. These effects have been noted both in populations which have ingested arsenic via drinking water and among people treated with large doses of arsenite for skin disorders. In a report by Pershagen and Vahter (1979), the authors, using the data from a patient population exposed to arsenic via Fowler's solution (Fierz, 1965), noted an increase in prevalence of hyperkeratosis with increasing dose of arsenic. The U.S. EPA is presently examining this information, along with information from other studies, in order to determine whether quantitative dose-response relationships, similar to those seen for skin cancer, can be established for these precancerous skin lesions.

9.3.2.4 Peripheral Neuropathological Effects and Cardiovascular Changes -- While the qualitative evidence for peripheral neurological effects and cardiovascular changes in arsenic-exposed populations is incontrovertible, the data are insufficient to establish quantitative dose-response relationships at the present time.

9.4 POPULATIONS AT SPECIAL RISK TO ARSENIC EXPOSURE

In reviewing the literature dealing with the acute, subacute and chronic effects of arsenic in children and adults, the evidence suggests that children may be at special risk for the effects of inorganic arsenic under conditions of acute or subacute exposure.

In earlier sections, reference was made to the outbreak of pediatric poisoning by arsenic in Japan due to the presence of arsenic in infant milk formula (Hamamoto et al., 1955). From the clinical reports published at the time of the mass poisoning as well as those from follow-up studies, a number of signs of central nervous system involvement were noted both at the time of the episode and much later, with the follow-up studies showing behavioral problems, abnormal brain wave patterns, marked cognitive deficits, and severe hearing loss in some of those children who survived the acute episode. Some

of these same tardive effects have also been noted in adults but appear to be a much less constant feature of arsenic-induced neurotoxic effects than are the peripheral neuropathies.

Because children consume more water per body weight than do adults, the daily intake of arsenic via drinking water per kilogram body weight would be greater in children. This may have implications regarding chronic exposure effects in children. Zaldivar (1977) developed a regression equation describing this relationship. It should be noted, however, that serious health effects due to chronic exposure of arsenic in drinking water have not been found at a greater frequency in children than adults.

Individuals residing in the vicinity of certain arsenic-emitting sources, e.g., certain types of smelters, may be at risk for increased arsenic intake because of both direct exposure to arsenic in air and indirect exposure via arsenic secondarily deposited from air onto soil or other human exposure media. The relative contribution of such indirect exposures to increased risk of these individuals for arsenic health effects is difficult to define due to the lack of information on this subject. However, it is most likely minimal in relation to the direct effects arising from inhalation of arsenic, including lung cancer.

As a large class of the general population at risk for increased arsenic intake, one would have to include cigarette smokers. However, it is not clear to what extent some increased arsenic intake from tobacco smoke poses a specific heightened health effect risk, although it is clear that internal indicator levels, e.g. blood arsenic, are somewhat elevated in the case of cigarette smokers relative to nonsmokers.

Risk Assessment Guidance for Superfund
Volume I: Human Health Evaluation Manual
(Part F, Supplemental Guidance for Inhalation Risk Assessment)

Final

Office of Superfund Remediation and Technology Innovation
Environmental Protection Agency
Washington, D.C.

REC 5247

TR 1932

TABLE OF CONTENTS

1. INTRODUCTION 1
- 1.1 Background 1
- 1.2 Purpose and Scope 2
- 1.3 Effects on Other Office of Superfund Remediation and Technology Innovation Guidance 3

2. BACKGROUND ON DERIVATION OF INHALATION TOXICITY VALUES 4
- 2.1 Application of Inhalation Dosimetry 4
  - 2.1.1 Default Approach - Extrapolation from Experimental Animal Data 5
  - 2.1.2 Default Approach - Extrapolation from Human Occupational Data 9
- 2.2 Derivation of the Inhalation Unit Risk 10
- 2.3 Derivation of the Reference Concentration 10

3. CHARACTERIZING EXPOSURE 13
- 3.1 Introduction 13
- 3.2 Estimating Exposure Concentrations for Assessing Cancer Risks 13
- 3.3 Estimating Exposure Concentrations for Calculating Hazard Quotients 14
  - 3.3.1 Step 1: Assess Duration 14
  - 3.3.2 Step 2: Assess Exposure Pattern 15
  - 3.3.3 Step 3: Estimate Exposure Concentration 17
- 3.4 Estimating Exposure Concentrations in Multiple Microenvironments 18
  - 3.4.1 Using Microenvironments to Estimate an Average Exposure Concentration for a Specific Exposure Period 18
  - 3.4.2 Estimating an Average Exposure Concentration Across Multiple Exposure Periods 19

4. SELECTING APPROPRIATE TOXICITY VALUES 20
- 4.1 Sources for Inhalation Toxicity Data 20
- 4.2 Recommended Procedure for Assessing Risk in the Absence of Inhalation Toxicity Values 21

5. ESTIMATING RISKS 22
- 5.1 Cancer Risks Characterized by an Inhalation Unit Risk 22
- 5.2 Hazard Quotients 24

6. EXAMPLE EXPOSURE SCENARIOS 24
- 6.1 Residential Receptor 24
- 6.2 Commercial-Industrial/Occupational Receptor 25
- 6.3 Construction Worker 25
- 6.4 Trespasser/Recreational Receptor 25

7. TARGET CONCENTRATIONS FOR SCREENING ANALYSIS OF INHALATION PATHWAYS 26
7.1 Target Contaminant Concentrations in Air 26
7.2 Screening Levels for Other Media 26
7.2.1 Soil Screening Levels 27
7.2.2 Tap Water Screening Levels 28
7.2.3 Soil Gas or Ground Water Screening Values for Vapor Intrusion 28

8. DEVELOPING AGGREGATE AND CUMULATIVE RISK ESTIMATES 28
8.1 Estimating Cumulative Risk and Hazards Across Multiple Chemicals 28
8.1.1 Cancer Risks 29
8.1.2 Hazard Quotients 29
8.2 Aggregating Risk and Hazard Quotients Across Exposure Routes 29

9. RISK CHARACTERIZATION 30
9.1 Highly Exposed or Susceptible Populations and Life Stages 30
9.1.1 Children 30
9.1.2 Workers 31
9.2 Uncertainties in Inhalation Risk Assessment 31
9.2.1 Development of Exposure Concentrations 32
9.2.2 Toxicity Assessment 32
9.2.3 Estimating Cancer Risks 33
9.2.4 Estimating Risk and Hazard from Multiple Chemicals and Exposure Pathways 33

ACKNOWLEDGEMENTS

This guidance was developed by the Inhalation Risk Workgroup, which included regional and headquarters staff in EPA's Office of Superfund Remediation and Technology Innovation (OSRTI), the Office of Research and Development (ORD), the Office of Children's Health Protection (OCHP), The Office of Air and Radiation (OAR), and the Office of Solid Waste and Emergency Response (OSWER). Dave Crawford of OSRTI headquarters and Michael Sivak of EPA Region 2 provided project management and technical coordination of its development.

OSRTI would like to acknowledge the efforts of all the Inhalation Risk Workgroup members who supported the development of the guidance by providing technical input regarding its content and scope:

Marcia Bailey, Region 10
Bob Benson, Region 8
Dave Crawford, OSWER/OSRTI
Arunas Draugelis, Region 5
Brenda Foos, OCHP
Gary Foureman, ORD/NCEA
Susan Griffin, Region 8
Ofia Hodoh, Region 4
Jennifer Hubbard, Region 3
Ann Johnson, OA/OPEI
Jeremy Johnson, Region 7
Kevin Koporec, Region 4
Sarah Levinson, Region 1
Deirdre Murphy, OAR/OAQPS
Henry Schuver, OSWER/OSW
Michael Sivak, Region 2
John Stanek, ORD/NCEA
Daniel Stralka, Region 9
Timothy Taylor, OSWER/OSW
John Whalan, ORD/NCEA
Erik Winchester, ORD/OSP

Former Members:
Cheryl Overstreet, Region 6
Neil Stiber, ORD/OSP

OSRTI would also like to acknowledge the efforts of the external peer review panel members who provided input on the draft version of the document:

Sandra Baird, Massachusetts Department of Environmental Protection
Selene Chou, Agency for Toxic Substances and Disease Registry
Lynne Haber, Toxicology Excellence for Risk Assessment
Anita Meyer, US Army Corps of Engineers
Peter Valberg, Gradient Corporation

Henry Roman, Eric Ruder, and Tyra Walsh of Industrial Economics, Incorporated in Cambridge, MA provided technical assistance to EPA in the development of this guidance under Contract Number 68-W-01-05.

LIST OF ACRONYMS

µg	Microgram
µm	Micrometer
ADAF	Age Dependent Adjustment Factor
AT	Averaging Time
ATSDR	Agency for Toxic Substances and Disease Registry
BMCL	Benchmark Concentration, Lower confidence limit
BMD	Benchmark Dose
BW	Body Weight
CA	Contaminant Concentration in Air

TB	Tracheobronchial
TOT	Total Respiratory System
UF	Uncertainty Factor
V_e	Minute Volume

1. INTRODUCTION

The Environmental Protection Agency's (EPA's) Superfund Program has updated its approach for determining risk from inhaled chemicals to be consistent with the inhalation dosimetry methodology described in *Methods for Derivation of Inhalation Reference Concentrations and Application of Inhalation Dosimetry* (USEPA, 1994; hereafter, the *Inhalation Dosimetry Methodology*).[1] This document provides Superfund site risk assessors with guidance that should help more consistently address the *Inhalation Dosimetry Methodology*.

This document outlines recommended processes consisting of a series of steps as well as recommended equations for EPA Regions to consider when estimating inhalation exposure and risk at Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) sites. This guidance is intended to provide a recommended methodology for consistently addressing the inhalation pathway in risk assessments for Superfund sites.

Some of the statutory provisions described in this document contain legally binding requirements. However, this document does not substitute for those provisions or regulations, nor is it a regulation itself. Thus, it cannot impose legally binding requirements on EPA, States, or the regulated community, and may not apply to a particular situation based upon the circumstances. Any decisions regarding a particular remedy selection decision will be made based on the statute and regulations, and EPA decisionmakers retain the discretion to adopt approaches on a case-by-case basis that differ from this guidance where appropriate. EPA may change this guidance in the future.

1.1 Background

EPA's *Risk Assessment Guidance for Superfund (RAGS), Part A* (USEPA, 1989; hereafter, *RAGS, Part A*) outlined a previously recommended approach for conducting site-specific baseline risk assessments for inhaled contaminants.[2] According to the original RAGS approach, the inhalation exposure estimate was typically derived in terms of a chronic, daily "air intake" (mg/kg-day) using the following general approach. The intake of the chemical was estimated as a function of the concentration of the chemical in air (CA), inhalation rate (IR), body weight (BW), and the exposure scenario. Age-specific values for BW and IR were used when evaluating childhood exposures. Table 1 presents the *RAGS, Part A* equation for calculating intake for inhalation exposure. Inhalation toxicity values were "converted" into similar units for the risk quantification step. Cancer risk was estimated by multiplying the chronic daily intake of the chemical from the air by the "inhalation cancer slope factor" (CSF_i); the Hazard Quotient (HQ) for non-cancer effects was estimated by dividing the intake of the chemical by an "inhalation reference dose" (RfD_i).[3]

The approach outlined in *RAGS, Part A* was developed before EPA issued the *Inhalation Dosimetry Methodology*, which describes the Agency's refined recommended approach for interpreting

---

[1] The *Inhalation Dosimetry Methodology* can be found at the following web address: http://cfpub.epa.gov/ncea/cfm/recordisplay.cfm?deid=71993.

[2] See sections 6.6.3, 7.2.3, 7.3.3, and 8.2 of *RAGS, Part A*.

[3] EPA defines an HQ in *RAGS, Part A* as: "The ratio of a single substance exposure level over a specified time period (e.g., subchronic) to a reference dose (RfD) for that substance derived from a similar exposure period" (USEPA, 1989).

REC 5255

TR 1940

inhalation toxicity studies in laboratory animals or studies of occupational exposures of humans to airborne chemicals. Under the *Inhalation Dosimetry Methodology*, the experimental exposures are typically extrapolated to a Human Equivalent Concentration (HEC), and a reference concentration (RfC) is typically calculated by dividing the HEC by uncertainty factors (UFs). As described in the Agency's *Guidelines for Cancer Risk Assessment* (USEPA, 2005a), the HEC developed in accordance with the *Inhalation Dosimetry Methodology* typically is also used in developing an inhalation unit risk (IUR) for cancer risk assessment (which may also be called an inhalation cancer slope factor).[4] The procedure that was used to calculate the published RfC or IUR is described in the Integrated Risk Information System (IRIS) profile or other toxicological reference document for a chemical.

TABLE 1
RAGS, PART A EQUATION DESCRIBING THE ESTIMATION OF INHALATION EXPOSURE

Equation	Location in RAGS, Part A
Intake (mg/kg-d) = CA x (IR/BW) x (ET x EF x ED)/AT	Exhibit 6-16, Page 6-44
Key: CA (mg/m^3) = contaminant concentration in air; IR (m^3/hr) = inhalation rate; BW (kg) = body weight; ET (hours/day) = exposure time; EF (days/year) = exposure frequency; ED (years) = exposure duration; and AT (days) = averaging time (period over which exposure is averaged).	

The Superfund Program has updated its inhalation risk paradigm to be compatible with the *Inhalation Dosimetry Methodology*, which represents the Agency's current methodology for inhalation dosimetry and derivation of inhalation toxicity values.[5] This document recommends that when estimating risk via inhalation, risk assessors should use the concentration of the chemical in air as the exposure metric (e.g., mg/m^3), rather than inhalation intake of a contaminant in air based on IR and BW (e.g., mg/kg-day).

1.2 Purpose and Scope

The intake equation described above (*RAGS, Part A*, Exhibit 6-16) is not consistent with the principles of EPA's *Inhalation Dosimetry Methodology* because the amount of the chemical that reaches the target site is not a simple function of IR and BW. Instead, the interaction of the inhaled contaminant with the respiratory tract is affected by factors such as species-specific relationships of exposure concentrations (ECs) to deposited/delivered doses and physiochemical characteristics of the inhaled contaminant. The *Inhalation Dosimetry Methodology* also considers the target site where the toxic effect occurs (e.g., the respiratory tract or a location in the body remote from the portal-of-entry) when applying dosimetric adjustments to experimental concentrations (USEPA, 1994). Therefore, this *RAGS, Part A* equation is not recommended for estimating exposures to inhaled contaminants.

---

[4] The phrase "inhalation cancer slope factor," as used in this guidance, refers generally to the risk per a measure of inhalation exposure. Inhalation exposure in cancer bioassays or occupational studies from which slope factors may be derived is most commonly expressed as an exposure concentration (e.g., µg agent/m^3 air). Please note that this differs from past use of the phrase "inhalation cancer slope factor" or "CSF_i" by the Superfund program to refer to a cancer slope expressed as an "inhalation intake" (e.g., *RAGS, Part A* (USEPA, 1989)).

[5] For additional information about the Superfund program's adoption of the *Inhalation Dosimetry Methodology*, please refer to the summary of a 2003 Superfund workshop on inhalation risk assessment: http://www.epa.gov/oswer/riskassessment/pdf/finalinhalationriskworkshop.pdf.

The purpose of this document is to provide a recommended approach for developing the information necessary to assist risk assessment and risk management decision-making at waste sites involving potential risks from inhalation exposures.[6, 7] This includes providing equations that may be used in conducting baseline risk assessments and in calculating risk-based concentrations (RBCs). It is intended that *RAGS, Part F* will replace those portions of *RAGS, Part A*, which addressed inhalation risk.

1.3 Effects on Other Office of Superfund Remediation and Technology Innovation Guidance

EPA recommends that the intake equation presented in *RAGS, Part A* (USEPA, 1989, Exhibit 6-16) should no longer be used when evaluating risk from the inhalation pathway. Implementation of a risk assessment approach consistent with the *Inhalation Dosimetry Methodology* will also affect the following guidance documents: *RAGS, Part B*, Section 3.3: Volatilization and Particulate Emission Factors (USEPA, 1991); and the Office of Solid Waste and Emergency Response's (OSWER's) *Draft Guidance for Evaluating the Vapor Intrusion to Indoor Air Pathway from Groundwater and Soils* (USEPA, 2002a; hereafter the *Vapor Intrusion Guidance*). EPA no longer recommends using the equations in Section 3.3 of *RAGS, Part B* nor the inhalation toxicity values generated using simple route-to-route extrapolation, such as those presented in the 2002 draft *Vapor Intrusion Guidance* and related documents.[8]

This guidance does not affect the equations pertaining to risk from inhaled chemicals in the *Soil Screening Guidance* (USEPA, 1996), Section 2.4, or the *Supplemental Guidance for Developing Soil Screening Levels for Superfund Sites* (USEPA, 2002b), Sections 4.2.3, 5.3.2 and Appendix B, other than to clarify that the IURs and RfCs used in the equations are based on continuous exposure (24 hours per day). If the exposure scenario of interest is less than 24 hours per day, the scenario-specific exposure time (ET) in hours per day should be used in the equations and the averaging time should be in units of hours (see Equations 6 and 8 in this document). *RAGS, Part D* (USEPA, 2001) is also not affected by *RAGS, Part F*, as it includes sufficient flexibility to accommodate the revisions described in this guidance. In addition, the screening values presented on the "Regional Screening Levels for Chemical Contaminants at Superfund Sites" screening level/preliminary remediation goal table are consistent with *RAGS, Part F* (USEPA, 2008a).[9] Readers can contact EPA headquarters with questions about the compatibility of specific Superfund documents with *RAGS, Part F*.

---

[6] Note that the assessment of risk from inhaled nanoparticles is outside the scope of this document.

[7] If a site contains asbestos contamination, risk assessors should contact EPA's Technical Review Workgroup for Metals and Asbestos for assistance.

REC 5257

TR 1942

2. BACKGROUND ON DERIVATION OF INHALATION TOXICITY VALUES

For all exposure routes, there are generally two approaches for deriving toxicity values. One involves the derivation of a reference value (e.g., RfC or RfD), while the other involves derivation of a predictive cancer risk estimate (e.g., an oral or inhalation CSF, such as an IUR). For the inhalation route, both approaches rely on EPA's *Inhalation Dosimetry Methodology* for the extrapolation of experimental concentrations to HECs. This extrapolation is described in Section 2.1 and its subsections. The approaches for deriving a toxicity value from the HEC are described in Sections 2.2 and 2.3 and differ depending on the type of toxicity value (e.g., RfC, IUR). This information is provided for background purposes only. **The procedures outlined in Section 2 are typically performed by IRIS chemical managers or by inhalation toxicologists at the National Center for Environmental Assessment's (NCEA's) Superfund Health Risk Technical Support Center (STSC) rather than as part of a baseline risk assessment.**

2.1 Application of Inhalation Dosimetry

The *Inhalation Dosimetry Methodology* recognizes a hierarchy of approaches that can be used for determining the HEC that is used to derive the RfC or IUR. Generally, the preferred approach is to use physiologically-based pharmacokinetic (PBPK) models.[10] With sufficient data, a PBPK model is capable of calculating the amount of the chemical that reaches the target organ in an animal from any exposure scenario and then estimating what human exposure would result in this same amount of chemical reaching the target organ (i.e., the HEC). PBPK models can also be used to derive continuous ECs from human and animal studies with less-than-continuous exposures. Because constructing a valid PBPK model is an information-intensive process that typically requires substantial chemical-specific data, this approach has rarely been used (USEPA, 2004b); an example can be found in the IRIS file for vinyl chloride (USEPA, 2000a). In cases where a complete PBPK model is not available, an intermediate model relying on certain chemical-specific data may be used (USEPA, 1994).[11]

If the database to support the preferred approach is inadequate, an alternative approach, called the Default Chemical Category-Specific Method can be used. This method incorporates the use of limited or categorical chemical-specific and physiological information. The default method is discussed below, followed by the procedures outlined in the *Inhalation Dosimetry Methodology* for deriving the RfC and IUR as they apply to the interpretation of animal and human data.

---

[10] EPA defines PBPK models in the IRIS glossary as a model that estimates the dose to a target tissue or organ by taking into account the rate of absorption into the body, distribution among target organs and tissues, metabolism, and excretion (USEPA, 2008b). For further information about PBPK modeling, please refer to *Approaches for the Application of Physiologically Based Pharmacokinetic Models and Supporting Data in Risk Assessment* (USEPA, 2006a).

[11] The *Inhalation Dosimetry Methodology* recognizes the existence of alternate approaches in addition to the two presented in this guidance. The PBPK approach is generally preferred. In the absence of such a model, alternate models may be more optimal than the default approach when default assumptions or parameters can be replaced by more detailed, biologically-motivated descriptions or actual data, respectively. For instance, a model may be considered more optimal if it incorporates chemical or species-specific information or if it accounts for mechanistic determinants. See Table 3-6 in the *Inhalation Dosimetry Methodology* for more details on the hierarchy of approaches (EPA, 1994, page 3-40).

2.1.1 Default Approach - Extrapolation from Experimental Animal Data

The default method involves a two-step procedure that uses limited or categorical chemical-specific and physiological information to calculate the HEC. First, the chosen point of departure (POD) from the experimental data for a chemical is adjusted to derive a concentration intended to represent an equivalent dose under conditions of continuous exposure (7 days a week, 24 hours a day).[12] In the second step, this concentration is then multiplied by a Dosimetric Adjustment Factor (DAF) to generate the HEC. Further details on each step are outlined below.

2.1.1.1 Duration Adjustment to Continuous Exposure

Most of the inhalation studies of laboratory animals used to derive RfCs and IURs involve an exposure regimen of four to six hours per day, five to seven days per week, for 13 weeks or more (equivalent to 10 percent or more of the lifetime of the animal). The POD concentration from an animal study is mathematically adjusted to reflect an equivalent dose under conditions of continuous exposure.[13] Adjustment of duration to a continuous exposure scenario is regularly applied as a default procedure to studies with repeated exposures but not to single-exposure inhalation toxicity studies in animals (USEPA, 1994). Operationally, this is accomplished by applying a c x t product (where "c" is concentration, and "t" is duration of exposure) for both the number of hours in a daily exposure period and the number of days per week that the exposure is experienced. For example, if exposure in a particular study was 6 hours per day, 5 days per week, the experimental exposure is multiplied by 6/24 x 5/7 to calculate an equivalent continuous exposure. The general equation provided in the *Inhalation Dosimetry Methodology* (USEPA, 1994, Equation 4-2) for calculating duration-adjusted exposure levels in mg/m^3 for experimental animals is presented below.

$NOAEL_{[ADJ]}$ = E x D x W **(Equation 1)**

Where:

$NOAEL_{[ADJ]}$ (mg/m^3) = the NOAEL or analogous exposure level obtained with an alternate approach (e.g., LOAEL, LEC_{10}), adjusted for duration of experimental regimen;
E (mg/m^3) = the NOAEL or analogous exposure level observed in the experimental study;
D (h/h) = number of hours exposed/24 hours; and
W (days/days) = number of days of exposure/7days.

Using the example above, the assumption is that the product of c x t, not concentration alone, is associated with the toxicity observed. This is roughly equivalent to implying that if an effect occurs from a chemical at an exposure of 6 hours per day at 40 parts per million (ppm), that same effect will

[12] Examples of PODs include the no-observed-adverse-effect level (NOAEL); the lowest-observed-adverse-effect level (LOAEL); Benchmark Concentration, Lower confidence limit (BMCL); and the Lower limit on an Effective Concentration using a 10 percent response level (LEC_{10}). For definitions of the various PODs, please refer to the IRIS glossary (http://www.epa.gov/ncea/iris/help_gloss.htm).

[13] Continuous exposure refers to 24 hours per day, 7 days per week.

occur at an exposure of 24 hours per day at 10 ppm.[14] Note that this adjustment always produces a lower concentration value than that administered to experimental animals. Thus, as stated in *A Review of the Reference Dose and Reference Concentration Processes* (hereafter, the *RfD/RfC Review*), application of this procedure results in an automatic margin of protectiveness for chemicals for which concentration alone may be the more appropriate dose metric, and it reflects the maximum dose for chemicals for which total or cumulative dose is the appropriate measure (USEPA, 2002c). If a different procedure is used to calculate the continuous exposure, it should be fully discussed in the relevant technical support document for the chemical (e.g., IRIS profile, Provisional Peer Reviewed Toxicity Values (PPRTVs) Assessment). For additional discussion, including the uncertainties associated with this approach, see Section 4.3.2 of the *Inhalation Dosimetry Methodology* and Section 4.4.2.1 of the *RfD/RfC Review* (USEPA, 2002c).

2.1.1.2 Dosimetric Adjustment to Human Equivalent Concentration

Typically, the adjusted POD concentration from the animal study is next converted to an HEC using the following equation (USEPA, 1994, Equation 4-3):

$NOAEL_{[HEC]} = NOAEL_{[ADJ]} \times DAF$ **(Equation 2)**

Where:

$NOAEL_{[HEC]}$ (mg/m^3) = the NOAEL or analogous exposure level obtained with an alternate approach, dosimetrically adjusted to an HEC;

$NOAEL_{[ADJ]}$ (mg/m^3) = the NOAEL or analogous exposure level obtained with an alternate approach, adjusted for duration of experimental regimen; and

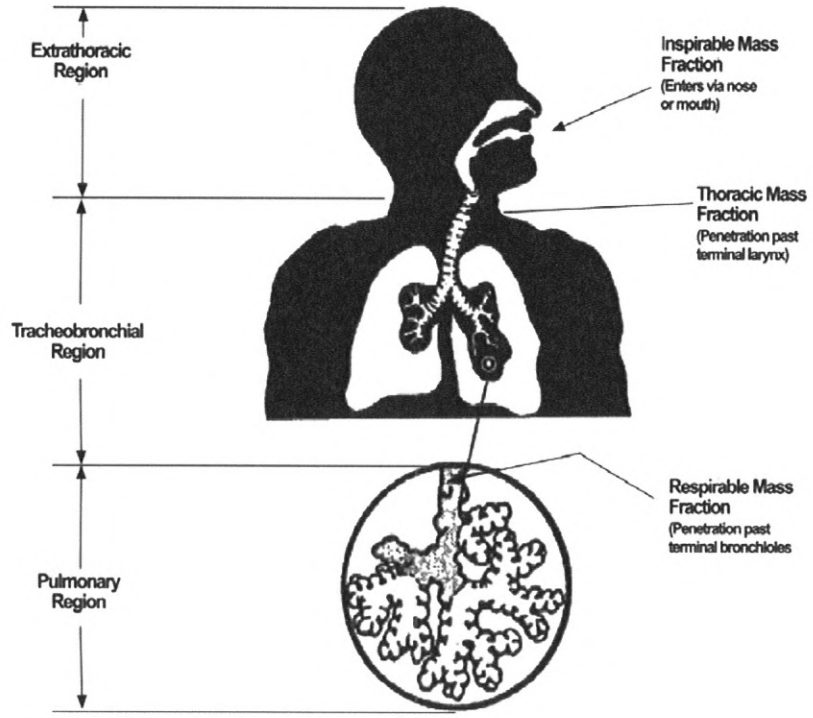
DAF = Dosimetric Adjustment Factor for the specific site of effects (e.g., respiratory tract region or extra-respiratory).

The DAF is typically based on ratios of animal and human physiologic parameters. The specific DAF used depends on the nature of the contaminant (e.g., particle or gas) and the target site where the toxic effect occurs (e.g., respiratory tract or a location in the body remote from the portal-of-entry). For example, the DAF can be based on either the Regional Gas Dose Ratio (RGDR), for gases with respiratory effects, or the Regional Deposited Dose Ratio (RDDR) for particles.

Table 2 provides information on the site of effects for the different chemical types. It also lists the physiologic parameters considered when calculating the DAF for specific regions of the body.[15] In addition, the table provides references to the equations from the *Inhalation Dosimetry Methodology* used in deriving the DAFs. Figure 1 provides a schematic of the human respiratory tract, illustrating each of the different regions.

---

[14] This assumption is based on Haber's Law, which states that "the incidence and/or severity of an adverse health effect depends on the total exposure to a potentially toxic substance. Total exposure (K) is the concentration of the substance (c) times the duration time of exposure (t), (i.e., $c \times t = K$)" (Gaylor, 2000).



[15] The three main regions of the respiratory tract include the following: 1) Extrathoracic (includes nose, mouth, nasopharynx, oropharynx, laryngopharynx, and larynx); 2) Tracheobronchial (includes trachea, bronchi, and bronchioles); and 3) Pulmonary (includes respiratory bronchioles, alveolar ducts, alveolar sacs and the alveoli).

TABLE 2
CONTAMINANT PROPERTIES AND DOSIMETRIC ADJUSTMENT FACTORS[a]

Chemical Type	Site of Effects	Parameters Considered in Derivation of DAF for Regions of the Body[b]	DAF Equation Numbers in Inhalation Dosimetry Methodology[c]
Category 1 Gases (e.g., acrolein, hydrogen fluoride, chlorine)	Respiratory	-Minute volume (ETh, TB) -Surface area (ETh, TB, PU) -Mass transport coefficient (TB, PU) -Fraction of inhaled chemical penetrating the respiratory region (PU) -Alveolar ventilation rate (PU)	4-18 (ETh), 4-21 & 4-22 (TB), 4-28 (PU)
Category 2 Gases (e.g., acetonitrile, xylene, propanol, isoamyl alcohol)	Respiratory and Remote	-Mass transport coefficients (ETh, TB) -Blood:gas partition coefficient (ET, TB, ER) -Cardiac output (ETh, TB, ER) -Alveolar ventilation rate (PU) -Surface Area (PU) -Minute volume (ER)	4-18 (ETh), 4-21 & 4-22 (TB), 4-28 (PU), 4-48 (ER)[d,e]
Category 3 Gases (e.g., benzene, styrene)	Remote	Blood:gas partition coefficient (ER)	4-48[d]
Particles	Respiratory and Remote	-Minute volume (TOT, ER) -Surface area (TOT) -Fractional deposition of particle (TOT, ER) -Body weight (ER) -Inhaled concentration (ER)	4-14 (TOT), 4-15 (ER)

[a] Due to the complexities inherent in evaluating the health effects associated with exposure to gases, no definitive or comprehensive list of Category 1, 2, or 3 gases is available. Risk assessors should consult with an inhalation toxicologist in order to classify a specific gas as Category 1, 2, or 3, since there is overlap between the sites of effects and the parameters considered in deriving the DAF for different regions of the respiratory tract.
[b] Additional discussion of the terms used in this table can be found in the *Inhalation Dosimetry Methodology*.
[c] The *Inhalation Dosimetry Methodology* provides equations for deriving DAFs for the different contaminant categories. The equations listed in this table are the default equations for each specific region in the body.
[d] This refers to Equation 4-48 that is found on page 4-60 of the *Inhalation Dosimetry Methodology*.
[e] The equations presented for Category 2 gases in the *Inhalation Dosimetry Methodology* contain errors. Therefore, this table refers to the equations for Category 1 and 3 gases, which are expected to cover respiratory and remote effects from Category 2 gases.
Acronyms: ETh = Extrathoracic; TB = Tracheobronchial; PU = Pulmonary; ER = Extra-respiratory; TOT = Total respiratory system.

FIGURE 1
HUMAN RESPIRATORY TRACT

Source: EPA (1994), Figure 3-1, Page 3-5.

Category 1 gases are highly water-soluble and/or are rapidly irreversibly reactive in the respiratory tract (e.g., acrolein, hydrogen fluoride, chlorine). They do not significantly accumulate in the blood, and therefore their effects are usually exclusively respiratory (USEPA, 1994). The DAF for Category 1 gases consists of an RGDR and is based on the animal to human ratio of the minute volume (V_e) divided by the surface area (SA) of the region of the respiratory tract where the effect occurs.[16] See Appendix A, Sections 1, 2, and 3 of this guidance for examples of specific Category 1 DAF equations.

[16] For the purposes of this document, the V_e is defined as the total ventilation per minute and equals the product of the tidal volume (the air volume entering or leaving the lungs with a single breath) and the respiratory frequency.

Category 3 gases are relatively water-insoluble and are unreactive in the respiratory tract (e.g., benzene, styrene). Their toxicity is generally at sites remote to the respiratory tract (USEPA, 1994). The DAF for Category 3 gases is based on the ratio of the animal blood:gas partition coefficient ($H_{b/g\text{-}animal}$) and the human blood:gas partition coefficient ($H_{b/g\text{-}human}$). See Appendix A, Section 4 of this guidance for an example of a Category 3 DAF equation.

Category 2 gases are moderately water-soluble and may be rapidly reversibly reactive or moderately to slowly irreversibly reactive in respiratory tract tissue (e.g., acetonitrile, xylene, propanol, isoamyl alcohol). These gases have potential for significant accumulation in the blood, so they can exhibit both respiratory and remote toxicity (USEPA, 1994). The DAF for respiratory effects of Category 2 gases consists of an RGDR and is based on the animal to human ratio of the V_e and the SA of the region of the respiratory tract where the effect occurs, as for Category 1 gases. The DAF for extra-respiratory (ER) effects of a Category 2 gas is based on the ratio of the $H_{b/g\text{-}animal}$ and the $H_{b/g\text{-}human}$, as for Category 3 gases.

Particles also vary by solubility and reactivity. However, the default equations used to estimate the predicted regional deposition fractions for particles are based on non-soluble, non-hygroscopic particles (USEPA, 1994, Section 4.3.5.3). The DAF for a particle causing an effect in the respiratory tract is the $RDDR_r$. The $RDDR_r$ is based on the animal to human ratio of the V_e and the fractional deposition of the particle in that region (F_r), divided by the SA_r of the region where the effect occurs. This derivation, from the *Inhalation Dosimetry Methodology,* conservatively assumes that 100 percent of the deposited dose remains in the respiratory tract; clearance mechanisms are not considered. The DAF for a particle causing an ER effect, the $RDDR_{ER}$, is based on the animal to human ratio of the V_e and the total deposition of the particle in the entire respiratory tract (F_{total}), divided by BW (USEPA, 1994). The $RDDR_{ER}$ assumes that 100 percent of the deposited dose in the entire respiratory tract is available for uptake into the systemic circulation. See Appendix A, Section 5 for examples of specific particle DAF equations.

2.1.2 Default Approach - Extrapolation from Human Occupational Data

When human data are available to derive an RfC, duration adjustments are often required to account for differences in exposure scenarios (e.g., extrapolation from an 8 hour/day occupational exposure to a continuous chronic exposure). The default approach recommended by the *Inhalation Dosimetry Methodology* for adjusting the POD concentration (e.g., the no observable adverse effect level (NOAEL)) obtained from human study data is provided below in Equation 3 (USEPA, 1994, Equation 4-49).[17,18]

[17] If sufficient data are available, a PBPK model or intermediate approach using chemical-specific information may be employed in preference to the default method for extrapolating human occupational data to an HEC.

[18] EPA's IRIS glossary defines an adverse effect as the following: "A biochemical change, functional impairment, or pathologic lesion that affects the performance of the whole organism, or reduces an organism's ability to respond to an additional environmental challenge" (USEPA, 2008b).

$NOAEL_{[HEC]}$ = NOAEL x (VEho/VEh) x 5 days/7 days **(Equation 3)**

Where: $NOAEL_{[HEC]}$ (mg/m^3) = the NOAEL or analogous exposure level obtained with an alternate approach, dosimetrically adjusted to an ambient HEC;
NOAEL (mg/m^3) = occupational exposure level (time-weighted average over an 8-hour exposure period);
VEho = human occupational default minute volume over 8 hours (10 m^3); and
VEh = human ambient default minute volume over 24 hours (20 m^3).

2.2 Derivation of the Inhalation Unit Risk

The default approach for determining predictive cancer risk recommended by EPA's *Guidelines for Carcinogen Risk Assessment* (USEPA, 2005a; hereafter, *Cancer Guidelines*) is a linear extrapolation from exposures observed in the animal or human occupational study.[19] This approach involves drawing a straight line from the POD to the origin. The default linear extrapolation approach is generally considered to be conservatively protective of public health, including sensitive sub-populations (USEPA, 2005a). The slope of this line is commonly called the slope factor, and when the units are risk per $\mu g/m^3$, it is also called the IUR. EPA defines an IUR in the IRIS glossary as "the upper-bound excess lifetime cancer risk estimated to result from continuous exposure to an agent at a concentration of 1 $\mu g/m^3$ in air" (USEPA, 2008b). Equation 4 below presents a linear extrapolation from a POD of 10 percent response (LEC_{10}).[20]

$IUR = 0.1/LEC_{10[HEC]}$ **(Equation 4)**

Where: IUR $(\mu g/m^3)^{-1}$ = Inhalation Unit Risk; and
$LEC_{10[HEC]}$ ($\mu g/m^3$) = the lowest effective concentration using a 10 percent response level, dosimetrically adjusted to an HEC.

2.3 Derivation of the Reference Concentration

EPA defines an RfC in the IRIS glossary as "an estimate (with uncertainty spanning perhaps an order of magnitude) of a continuous inhalation exposure to the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious effects during a lifetime" (USEPA, 2008b). The RfC is derived after a review of the health effects database for a chemical and identification of the most sensitive and relevant endpoint along with the principal study or studies demonstrating that endpoint. EPA Chemical Managers use UFs to account for recognized

[19] According to the *Cancer Guidelines*, "[a] nonlinear approach should be selected when there are sufficient data to ascertain the mode of action [MOA] and conclude that it is not linear at low doses and the agent does not demonstrate mutagenic or other activity consistent with linearity at low doses" (USEPA, 2005a, page 3-22). In addition, [l]inear extrapolation should be used when there are MOA data to indicate that the dose-response curve is expected to have a linear component below the POD" (USEPA, 2005a, page 3-21). This information will appear on the IRIS profile or other toxicological information source for a chemical. Chemicals with a mutagenic MOA are thought to pose a higher risk during early life. Procedures for assessing cancer risk from these chemicals are outlined in Section 5.1.

[20] The POD used in Equation 4 is an LEC_{10}, which is the lower 95 percent confidence limit on the concentration corresponding to a 10 percent response rate (i.e., the EC_{10}). Other PODs may be substituted for this value, which could be associated with alternative response levels (e.g., 1 percent, 5 percent).

uncertainties in the extrapolations from the experimental data conditions to an estimate appropriate to the assumed human scenario (USEPA, 1994). See Table 3 for a description of the standard UFs. The formula used for deriving the RfC from the HEC is provided below.

$RfC = NOAEL_{[HEC]}/(UF)$[1] **(Equation 5)**

Where: RfC (mg/m^3) = Reference Concentration
$NOAEL_{[HEC]}$ (mg/m^3) = The NOAEL or analogous exposure level obtained with an alternate approach, dosimetrically adjusted to an HEC; and
UF = Uncertainty factor(s) applied to account for the extrapolations required from the characteristics of the experimental regimen.

[1] Some toxicological information sources for RfCs will incorporate an additional factor to account for deficiencies in the available data set, called a modifying factor (MF). In 2002, however, EPA published the *RfD/RfC Review,* which recommended that the use of MFs be discontinued because their purpose is "sufficiently subsumed in the general database UF" (USEPA, 2002c, page xviii). Therefore, RfCs published subsequent to this document will not include MFs.

TABLE 3
THE USE OF UNCERTAINTY FACTORS IN DERIVING AN INHALATION REFERENCE CONCENTRATION

Standard UFs	Processes Considered in the UF Purview
H = Human to sensitive human: Extrapolation of valid experimental results from studies using prolonged exposure to average healthy humans. Intended to account for the variation in sensitivity among the members of the human population.	-Pharmacokinetics/Pharmacodynamics -Sensitivity[2] -Differences in body weight (age, obesity) -Concomitant exposures -Activity pattern -Does not account for idiosyncrasies
A = Animal to human: Extrapolation from valid results of long-term studies on laboratory animals when results of studies of human exposure are not available or are inadequate. Intended to account for the uncertainty in extrapolating laboratory animal data to the case of average healthy humans.	-Pharmacokinetics/Pharmacodynamics -Relevance of laboratory animal model -Species sensitivity
S = Subchronic to chronic: Extrapolation from less-than-chronic exposure results on laboratory animals or humans when there are no useful long-term human data. Intended to account for the uncertainty in extrapolating from less than chronic NOAELs to chronic NOAELs.	-Accumulation/Cumulative damage -Pharmacokinetics/ Pharmacodynamics -Severity of effect -Recovery -Duration of study -Consistency of effect with duration
L = LOAEL to NOAEL: Derivation from a LOAEL instead of a NOAEL. Intended to account for the uncertainty in extrapolating from LOAELs to NOAELs.	-Severity -Pharmacokinetics/Pharmacodynamics -Slope of dose-response curve -Trend, consistency of effect -Relationship of endpoints -Functional vs. histopathological evidence -Exposure uncertainties
D = Incomplete to complete data: Extrapolation from valid results in laboratory animals when the data are "incomplete." Intended to account for the inability of any single laboratory animal study to adequately address all possible adverse outcomes in humans.[1]	-Quality of critical study -Data gaps -Power of critical study/supporting studies -Exposure uncertainties

[1] The *RfD/RfC Review* indicates that this UF accounts for the potential for deriving an underprotective RfD/RfC as a result of an incomplete characterization of the chemical's toxicity or if the existing data suggest that a lower reference value might result if additional data were available (considering both the lacking and available data for particular organ systems as well as life stage) (USEPA, 2002c).

[2] The *RfD/RfC Review* also stresses that susceptible populations and life stages are accounted for with this UF (USEPA, 2002c).

REC 5266

TR 1951

3. CHARACTERIZING EXPOSURE

3.1 Introduction

This section describes an approach for characterizing exposure in a baseline risk assessment that is consistent with the *Inhalation Dosimetry Methodology*. The approach involves the estimation of exposure concentrations (ECs) for each receptor exposed to contaminants via inhalation in the risk assessment. ECs are time-weighted average concentrations derived from measured or modeled contaminant concentrations in air at a site, adjusted based on the characteristics of the exposure scenario being evaluated.[21,22]

Equations for estimating ECs are provided below. This document does not provide default input values for the exposure parameters referenced in these equations. EPA recommends the use of site-specific exposure values consistent with the exposure pathways and receptors at a site wherever practicable and appropriate. If a risk assessor opts to rely on default exposure input values, current Superfund-supported values may be found at the exposure assessment portion of the Superfund website: (http://www.epa.gov/oswer/riskassessment/superfund_hh_exposure.htm).

3.2 Estimating Exposure Concentrations for Assessing Cancer Risks

The estimation of an EC when assessing cancer risks characterized by an IUR involves the CA measured at an exposure point at a site as well as scenario-specific parameters, such as the exposure duration and frequency.[23] The EC typically takes the form of a CA that is time-weighted over the duration of exposure and incorporates information on activity patterns for the specific site or the use of professional judgment. The equation for estimating an EC for use with an IUR is presented below.

---

[21] The default method for deriving inhalation toxicity values also involves calculating time-weighted ECs, as discussed in Sections 2.1.1.1 and 2.1.2.

[22] The ECs in this document are in units of $\mu g/m^3$. Inhalation toxicity values presented on IRIS are typically expressed in units of $\mu g/m^3$ or mg/m^3, which are mass units. Some regulatory contexts require the use of volumetric units such as ppm. The conversion from mass units to volumetric units depends on the molecular weight (MW) of the material as well as the ambient temperature and atmospheric pressure. To convert from ppm to mg/m^3, the following equation can be used: $\frac{ppm \times MW}{V} = mg/m^3$; where MW is the molecular weight of the gas and V is the volume of 1 gram molecular weight of the airborne contaminant. This is derived by the formula V = RT/P; where R is the ideal gas constant, T is the temperature in Kelvin (K = 273.16 + T°C) and P is the pressure in mm Hg. The value of R is 62.4 when T is in Kelvin, (K = 273.16 + T°C), the pressure is expressed in units of mm Hg and the volume is in liters. The value of R differs if the temperature is expressed degrees Fahrenheit (°F) or if other units of pressure are used (e.g., atmospheres, kilopascals).

[23] ECs are typically based on either estimated (i.e., modeled) or measured contaminant concentrations in air.

EC = (CA x ET x EF x ED)/AT **(Equation 6)**

Where:
EC ($\mu g/m^3$) = exposure concentration;
CA ($\mu g/m^3$) = contaminant concentration in air;
ET (hours/day) = exposure time;
EF (days/year) = exposure frequency;
ED (years) = exposure duration; and
AT (lifetime in years x 365 days/year x 24 hours/day) = averaging time

3.3 Estimating Exposure Concentrations for Calculating Hazard Quotients

When estimating ECs for non-cancer or cancer hazards characterized by an HQ, risk assessors should match each exposure scenario at a site to the appropriate EC equation, based on the scenario duration and frequency of exposure.[24] Figure 2 presents a flowchart to assist risk assessors with this process and provides recommended equations that can be used to estimate the EC for each type of scenario.[25] As shown in Figure 2, the recommended process for estimating ECs to be used in calculating an HQ involves the following three steps: 1) assess the duration of the exposure scenario; 2) assess the exposure pattern of the exposure scenario; and 3) estimate the scenario-specific EC.

3.3.1 Step 1: Assess Duration

The first step in the recommended process of estimating an EC for use in calculating an HQ involves assessing the duration of the exposure scenario at a site. Step 1 in Figure 2 indicates that the risk assessor first should decide whether the duration of the exposure scenario is generally acute, subchronic, or chronic. Toxicologists have long been aware that effects from a single or short-term exposure can differ markedly from effects resulting from repeated exposures. The response by the exposed person depends upon factors such as whether the chemical accumulates in the body, whether it overwhelms the body's mechanisms of detoxification or elimination, or whether it produces irreversible effects (Eaton & Klaassen, 2001). Therefore, ideally, the chemical-specific elements of metabolism and kinetics, reversibility of effects, and recovery time should be considered as part of this recommended process when defining the duration of a site-specific exposure scenario.

[24] Traditionally, the HQ approach was limited to non-cancer hazard assessment. However, the HQ approach may also be appropriate for carcinogens with a non-linear mode of action. The 2005 *Cancer Guidelines* state the following on this subject: "For cases where the tumors arise through a nonlinear mode of action, an oral reference dose or an inhalation reference concentration, or both, should be developed in accordance with EPA's established practice for developing such values ... this approach expands the past focus of such reference values (previously reserved for effects other than cancer) to include carcinogenic effects determined to have a nonlinear mode of action" (USEPA, 2005a; page 3-24).

[25] Figure 2 was developed for the evaluation of inhalation exposures. While the concepts presented in this flowchart may be useful for assessing other exposure routes (e.g., oral or dermal), these other routes are beyond the scope of this document, and therefore, are not explicitly considered. Caution should be used when using Figure 2 to evaluate other exposure routes, as considerations beyond those outlined in the flowchart may apply (e.g., time to reach steady state for dermal exposures).

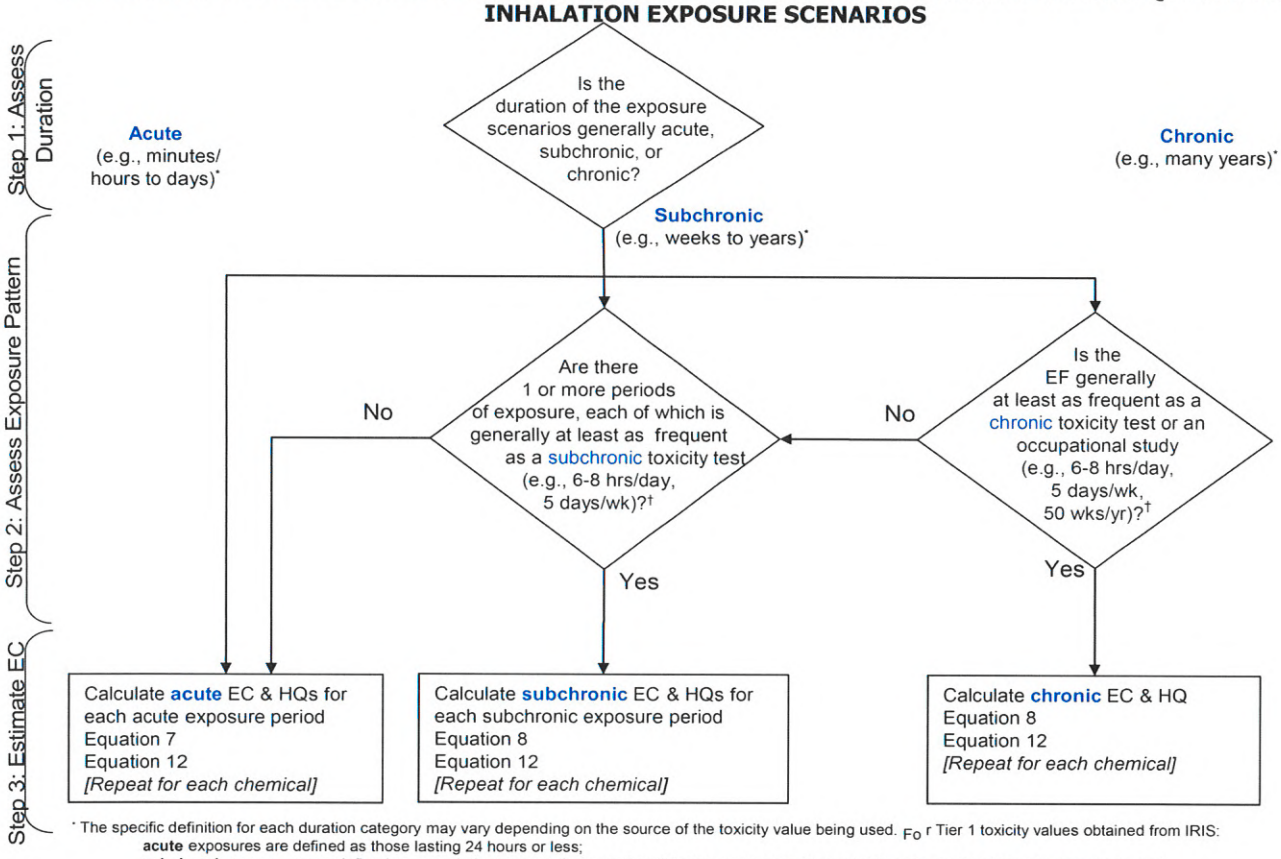
To the extent possible, exposure durations (EDs) evaluated in a site-specific risk assessment should be consistent with the ED represented by the toxicity value. However, frequencies or durations of human exposures often are not as clearly defined as those in animal studies with controlled exposures, particularly for intermittent exposures. For example, the emission of some volatile chemicals into the ambient air may vary with temperature and season, providing fluctuating exposures for humans living near the source. Therefore, risk assessors should use best professional judgment to determine if the ED in a given scenario is reasonably similar to the duration associated with the toxicity value. Risk assessors should describe the uncertainties associated with their choice of toxicity value in the risk characterization section of the risk assessment (see Section 9.2.2 of this document). For situations where duration-appropriate toxicity values are not available, please follow the procedures outlined in Section 4.2 and Appendix C of this document.

The specific definition for each exposure duration category may vary depending on the source of the toxicity value being used. For Tier 1 toxicity values obtained from EPA's IRIS database, acute exposures are defined as lasting 24 hours or less; subchronic exposures are defined as repeated exposures by the oral, dermal, or inhalation route for more than 30 days, up to approximately 10 percent of the human lifespan; and chronic exposures are defined as repeated exposures for more than approximately 10 percent of the human lifespan (USEPA, 2008b).[26, 27]

After deciding which duration the exposure scenario most closely matches, risk assessors should then proceed to Step 2, following the path of the selected duration. Note that if an acute duration is selected, risk assessors should proceed directly to Step 3 to estimate an acute EC for each acute exposure period.

3.3.2 Step 2: Assess Exposure Pattern

Step 2 of the recommended process for estimating an EC for use in a hazard quotient involves assessing the exposure pattern for each exposure scenario at a site. This entails comparing the exposure time and frequency at a site to that of a typical subchronic or chronic toxicity test.[28]



---

[26] Note that other sources of toxicity values may define exposures differently. For example, the Agency for Toxic Substances and Disease Registry (ATSDR) (which publishes Minimal Risk Levels (MRLs)) defines acute exposures as occurring from one to 14 days, intermediate exposures as greater than 14 to 364 days, and chronic exposures as 365 days or longer. However, the toxicity values are based on the same underlying toxicological concepts described in this section.

[27] Exposures with a duration lasting between 24 hours and 30 days should be treated as subchronic for the purposes of this document.

[28] Exposure regimens vary from study to study. Risk assessors should use best professional judgment to determine if the exposure pattern in a given scenario is reasonably similar to a typical regimen for a subchronic or chronic study.

FIGURE 2
RECOMMENDED PROCEDURE FOR DERIVING EXPOSURE CONCENTRATIONS AND HAZARD QUOTIENTS FOR INHALATION EXPOSURE SCENARIOS

* The specific definition for each duration category may vary depending on the source of the toxicity value being used. For Tier 1 toxicity values obtained from IRIS:
acute exposures are defined as those lasting 24 hours or less;
subchronic exposures are defined as repeated exposures for more than 30 days, up to approximately 10 percent of the life span in humans; and
chronic exposures are defined as repeated exposures for more than approximately 10 percent of the life span in humans (EPA, 2008b).
For the purposes of this document, short-term exposures, defined by the IRIS glossary as repeated exposures for more than 24 hours, up to 30 days, should be treated as subchronic.

† Exposure regimens vary from study to study. Risk assessors should use best professional judgment to determine if the exposure pattern in a given scenario is reasonably similar to a typical regimen for a chronic or subchronic study.

For exposure scenarios with a subchronic duration, risk assessors should follow the center path on the flowchart. Step 2 in this path asks whether there are one or more periods of exposure, each of which is generally as frequent as a subchronic toxicity test (e.g., 6-8 hours per day, 5 days per week). If the exposure scenario matches this description, risk assessors should proceed to Step 3 and estimate a subchronic EC for each subchronic exposure period. However, if the exposure pattern contains periods that are significantly shorter and/or involve significantly less frequent exposures than indicated in the flow chart, risk assessors should derive acute ECs for each of these exposure periods. If it is difficult to determine whether a specific exposure scenario is best modeled as a subchronic exposure or as a series of independent acute exposures, due to uncertainty in the time required to return to baseline following exposure, risk assessors may want to derive ECs using both approaches.

If the exposure scenario has a chronic duration, risk assessors should follow the right hand path on the flowchart. Step 2 in this path asks whether the exposure frequency (EF) is generally as frequent as a chronic animal toxicity test or a human occupational study (e.g., 6-8 hours per day, 5 days per week, for 50 weeks per year). If the exposure scenario matches this description, risk assessors should proceed to Step 3 and estimate a single chronic EC. However, if the scenario differs significantly from this pattern, risk assessors should proceed to the second question under the subchronic duration path and proceed as outlined above.

3.3.3 Step 3: Estimate Exposure Concentration

Step 3 of the recommended process involves estimating the EC for the specific exposure scenario based on the decisions made in Steps 1 and 2. For acute exposures, the EC is equal to the CA. Risk assessors can estimate an acute EC for each acute exposure period at a site using Equation 7. For longer-term exposures, risk assessors should take into consideration the exposure time, frequency, and duration for each receptor being evaluated as well as the period over which the exposure is averaged (i.e., the averaging time (AT)) to arrive at a time-weighted EC. If there are one or more exposure periods that are generally as frequent as a subchronic toxicity test, risk assessors should use Equation 8 to estimate a subchronic EC for each of these exposure periods. (Exposure periods with significantly less frequency should be treated as acute exposures.) If the exposure pattern is generally as frequent as a chronic toxicity test of an occupational study, risk assessors should use Equation 8 to estimate a single chronic EC for the duration of the exposure.

Acute Exposures

EC = CA **(Equation 7)**

Where: EC ($\mu g/m^3$) = exposure concentration;
CA ($\mu g/m^3$) = contaminant concentration in air;

Chronic or Subchronic Exposures

EC = (CA x ET x EF x ED)/AT **(Equation 8)**

Where:
EC ($\mu g/m^3$) = exposure concentration;
CA ($\mu g/m^3$) = contaminant concentration in air;
ET (hours/day) = exposure time;
EF (days/year) = exposure frequency;
ED (years) = exposure duration; and
AT (ED in years x 365 days/year x 24 hours/day) = averaging time

Note: If the duration of the exposure period is less than one year, the units in the above equation can be changed to the following: EF (days/week); ED (weeks/exposure period); and AT (hours/exposure period).

It is important to use the EC equation that most closely matches the exposure pattern and duration at a site. For instance, if the exposure pattern at a site consists of a series of short (e.g., 4-hour) periods of high exposure separated by several days of no exposure, the approach outlined above recommends estimating an acute EC for each acute exposure period. If the chronic EC equation (Equation 8) were to be used instead, the result would be an average EC value that may lead to an underestimate of risk since the inhaled concentrations could be higher than acute toxicity values during periods of exposure.

3.4 Estimating Exposure Concentrations in Multiple Microenvironments

When detailed information on the activity patterns of a receptor at a site is available, risk assessors can use these data to estimate the EC for either non-carcinogenic or carcinogenic effects. The activity pattern data describe how much time a receptor spends, on average, in different microenvironments (MEs), each of which may have a different contaminant concentration level.[29] By combining data on the contaminant concentration level in each ME and the activity pattern data, the risk assessor can calculate a time-weighted average EC for a receptor. Because activity patterns (and hence, MEs) can vary over a receptor's lifetime, EPA recommends that risk assessors pursuing the ME approach first calculate a time-weighted average EC for each exposure period characterized by a specific activity pattern (e.g., separate ECs for a school-aged child resident and a working adult resident). These exposure period-specific ECs can then be combined into a longer term or lifetime average EC by weighting the EC by the duration of each exposure period. The following sections further explain these two steps.

3.4.1 Using Microenvironments to Estimate an Average Exposure Concentration for a Specific Exposure Period

The ME approach can be used to estimate an average EC for a particular exposure period during which a receptor has a specified activity pattern. As a simplified example, a residential receptor may

[29] EPA defines a microenvironment in *Air Quality Criteria for Particulate Matter: Volume II* as a defined space that can be treated as a well-characterized, relatively homogeneous location with respect to pollutant concentration for a specified time period (e.g., rooms in homes, restaurants, schools, offices, inside vehicles, or outdoors) (USEPA, 2004b).

be exposed to a higher concentration of a contaminant in air in the bathroom for 30 minutes per day while showering, and exposed to a lower concentration in the rest of the house for the remaining 23.5 hours per day. In this case, risk assessors can use the CA value experienced in each ME weighted by the amount of time spent in each ME to estimate an average EC for the period of residency in that house using Equation 9.[30] This approach may also be used to address exposures to contaminants in outdoor and indoor environments at sites where both indoor and outdoor samples have been collected or where the vapor intrusion pathway has been characterized.

$$EC_j = \sum_{i=1}^{n} (CA_i \times ET_i \times EF_i) \times ED_j / AT_j \qquad \textbf{(Equation 9)}$$

Where:
EC_j ($\mu g/m^3$) = average exposure concentration for exposure period j;
CA_i ($\mu g/m^3$) = contaminant concentration in air in ME i;
ET_i (hours/day) = exposure time spent in ME i;
EF_i (days/year) = exposure frequency for ME i;
ED_j (years) = exposure duration for exposure period j; and
AT_j (hours) = averaging time = ED_j x 24 hours/day x 365 days/year.

3.4.2 Estimating an Average Exposure Concentration Across Multiple Exposure Periods

To derive an average EC for a receptor over multiple exposure periods, the average EC from each period (as calculated above in Equation 9) can be weighted by the fraction of the total exposure time that each period represents, using Equation 10. For example, when estimating cancer risks, the risk assessor may calculate a lifetime average EC where the weights of the individual exposure periods are the duration of the period, ED_j, divided by the total lifetime of the receptor. Alternatively, when estimating an HQ, risk assessors can use Equation 10 to calculate less-than-lifetime average ECs across multiple exposure periods. In that case, the AT will equal the sum of the individual EDs for all of the exposure periods.

$$EC_{LT} = \sum_{i=1}^{n} (EC_j \times ED_j) / AT \qquad \textbf{(Equation 10)}$$

Where:
EC_{LT} ($\mu g/m^3$) = long-term average exposure concentration;
EC_j ($\mu g/m^3$) = average exposure concentration of a contaminant in air for exposure period j;
ED_j (years) = duration of exposure period j; and
AT (years)[1] = averaging time.

[1] When evaluating cancer risk, the AT is equal to lifetime in years. When evaluating non-cancer hazard, the AT is equal to the sum of the EDs for each exposure period.

[30] If one or more MEs involve acute exposures, risk assessors should conduct a supplemental analysis comparing the CA for each of those MEs to a corresponding acute toxicity value to ensure that receptors are protected from potential acute health effects.

4. SELECTING APPROPRIATE TOXICITY VALUES

After characterizing the exposure scenarios and estimating ECs for each receptor at a site, the risk assessor should select appropriate inhalation toxicity values for each inhaled contaminant. For estimating cancer risks, this typically involves identifying and evaluating available published cancer potency estimates. For estimating HQs, this typically involves identifying and evaluating reference values that match the characterization of the exposure scenario from Figure 2 (i.e., acute, subchronic, or chronic reference values).

This section provides guidance for the selection of toxicity values appropriate for assessing risk under inhalation exposure scenarios. It describes sources for the most current inhalation data and provides guidance for proceeding when published inhalation toxicity data are not available.

4.1 Sources for Inhalation Toxicity Data

The OSWER Directive, *Human Health Toxicity Values in Superfund Risk Assessment* (USEPA, 2003), provides a recommended hierarchy of toxicological data sources to guide risk assessors when selecting appropriate toxicity values. This document sets out a recommended three-tiered framework for selecting human toxicity values. Tier 1 consists of EPA's IRIS, Tier 2 consists of EPA's PPRTVs, and Tier 3 includes other toxicity values as recommended by NCEA, such as the California EPA toxicity values, the Agency for Toxic Substances and Disease Registry's (ATSDR's) Minimal Risk Levels (MRLs), and Health Effects Assessment Summary Table (HEAST) toxicity values. Priority in Tier 3 should be given to sources that are the most current and those that are peer reviewed. Consultation with the Superfund Headquarters office is recommended regarding the use of Tier 3 values for Superfund response decisions when the contaminant appears to be a risk driver for the site.

The most up-to-date information on Superfund-supported cancer potency estimates and chronic and subchronic cancer and non-cancer reference values for inhaled contaminants are available on the Superfund risk assessment website (www.epa.gov/oswer/riskassessment/superfund_toxicity.htm). Superfund-recommended sources for acute non-cancer toxicity values can be found at www.epa.gov/oswer/riskassessment/superfund_acute.htm.[31]

In situations where the desired reference value (e.g., acute, subchronic, chronic) is not available, risk assessors may use a reference value based on the next longer duration of exposure as a conservative estimate that would be protective for a shorter-term ED (USEPA, 2002c). For example, if a risk assessor determines that an ED at a site is subchronic, but no subchronic toxicity value is available, a chronic RfC can be used to assess hazard.

EPA recommends that toxicity values published in Superfund-supported sources should generally be used in the risk equations presented in this guidance, without modification. This includes IURs on IRIS that were calculated from oral values using a default ventilation rate and BW (see Appendix B for a list of these chemicals). It is not generally appropriate to make adjustments to these values

[31] In selecting an acute toxicity value, risk assessors should consider the duration associated with their estimate of exposure (e.g., a 1-hour versus a 24-hour air sample). Use of a toxicity value specified for a longer duration than that of the exposure estimate may overestimate hazard, while the use of a shorter duration acute reference value may underestimate hazard.

REC 5274

TR 1959

based on IR and BW using the intake equation, because the amount of the chemical that reaches the target site through the inhalation pathway is not a simple function of these parameters (see Section 1.2). Use of the toxicity values listed in Appendix B should be noted in the uncertainty section of the risk assessment (see Section 9).

4.2 Recommended Procedures for Assessing Risk in the Absence of Inhalation Toxicity Values

The following section provides guidance on recommended procedures for situations where inhalation toxicity values are not available in any of the toxicity data sources described in Section 4.1.

If RfC and IUR values are not available for an inhaled contaminant, risk assessors should first contact NCEA's STSC for guidance.[32] Risk assessors working on Superfund sites can contact STSC to determine whether a provisional peer-reviewed toxicity value (PPRTV) exists for a contaminant; if not, the risk assessor, in cooperation with the appropriate EPA Regional office may request that STSC develop a PPRTV document or that STSC develop an inhalation toxicity value as a "consult". The latter would be specific to the site in question only. Additional information on STSC's current process for developing alternative toxicity values is described in Appendix C.

If STSC indicates that no quantitative toxicity information for the inhalation route is available, the risk assessor should conduct a qualitative evaluation of this exposure route. The risk assessor should discuss in the uncertainty section of the risk assessment report the implications of not quantitatively assessing risks due to inhalation exposures to chemicals lacking inhalation toxicity data. See the section on Risk Characterization (Section 9) in this guidance for more information.

Performing simple route-to-route extrapolation without the assistance of STSC is generally not appropriate because hazard may be misrepresented when data from one route are substituted for another without any consideration of the pharmacokinetic differences between the routes (USEPA, 1998). The following circumstances, outlined in the *Inhalation Dosimetry Methodology* (page 4-6), are specific examples of situations when route-to-route extrapolation from oral toxicity values might not be appropriate, even for use during screening:

- When groups of chemicals are expected to have different toxicity by the two routes – for example, metals, irritants, and sensitizers;
- When a first-pass effect by the respiratory tract is expected;
- When a first-pass effect by the liver is expected;
- When a respiratory tract effect is established, but dosimetry comparison cannot be clearly established between the two routes;
- When the respiratory tract was not adequately studied in the oral studies; and
- When short-term inhalation studies, dermal irritation, in vitro studies, or characteristics of the chemical indicate the potential for portal-of-entry effects at the respiratory tract, but studies themselves are not adequate for inhalation toxicity value development.

[32] All contact with STSC should be performed by an EPA regional risk assessor. States and other entities should first contact their EPA regional risk assessor with questions on inhalation toxicity values. Regional risk assessors can then contact STSC on their behalf.

REC 5275

TR 1960

The *Cancer Guidelines* (USEPA, 2005a) includes the following statement regarding route-to-route extrapolation:

> "When a qualitative extrapolation can be supported, quantitative extrapolation may still be problematic due to the absence of adequate data. The differences in biological processes among routes of exposure (oral, inhalation, dermal) can be great because of, for example, first-pass effects and different results from different exposure patterns. There is no generally applicable method for accounting for these differences in uptake processes in a quantitative route-to-route extrapolation of dose-response data in the absence of good data on the agent of interest. Therefore, route-to-route extrapolation of dose data relies on a case-by-case analysis of available data" (page 3-10).

5. ESTIMATING RISKS

This section provides updated equations recommended for estimating excess cancer risks and HQs from inhaled contaminants of concern at Superfund sites. Please see Section 8.2.1 of *RAGS, Part A* for further information about how to interpret calculated excess cancer risks and HQs.

5.1 Cancer Risks Characterized by an Inhalation Unit Risk

The excess cancer risk for a receptor exposed via the inhalation pathway can be estimated with the following equation:

Risk = IUR x EC **(Equation 11)**

Where: IUR $(\mu g/m^3)^{-1}$ = Inhalation Unit Risk; and
EC $(\mu g/m^3)$ = exposure concentration (See Equation 6).

When estimated ECs are above the POD used for the low dose extrapolation described in Section 2.3, a linear concentration-response relationship may not hold.[33] In such situations, the risk assessor should not use toxicity values developed through low dose extrapolation techniques. Instead, the risk assessor may report semi-quantitative risk estimates (e.g., risks are greater than 10^{-2}) or estimate risk using the original model underlying the toxicity value, which can be found in the technical support document for the value (e.g., IRIS profile, PPRTV Assessment).

When estimating cancer risks for children, risk assessors should be aware of chemicals that pose a higher risk of cancer when exposure occurs during early life. If evidence exists suggesting differences in risk across age groups for a chemical, this typically will be considered in the derivation of the toxicity value and described in the chemical's technical support document.

[33] Reviews of chemical-specific IRIS files indicate that the risk level corresponding to the concentration level above which the IUR should not be used often falls at or near 10^{-2}. However, this risk level varies by chemical and, therefore, risk assessors should refer to the toxicity value's technical support document for information on the concentration range for which the IUR was intended to be used.

REC 5276

TR 1961

Chemicals that have been determined to cause cancer by a mutagenic mode of action (MOA) are thought to pose a higher risk during early life. An EPA-recommended procedure exists for assessing risks from these chemicals. Figure 3 summarizes the recommendations of the *Supplemental Guidance for Assessing Susceptibility from Early-Life Exposure to Carcinogens* (USEPA, 2005b; hereafter *Supplemental Cancer Guidelines*) on how to adjust childhood risk calculations to account for chemicals with a mutagenic MOA for carcinogenicity. Please refer to the *Supplemental Cancer Guidelines* (USEPA, 2005b) for a list of chemicals with a mutagenic MOA that were used in the development of that document.

In addition, EPA's website for the "Handbook for Implementing the Supplemental Cancer Guidance at Waste and Cleanup Sites" contains an up-to-date list of chemicals that EPA has determined to have a mutagenic MOA (http://www.epa.gov/oswer/riskassessment/sghandbook/index.htm). As chemicals receive new assessments for mutagenicity, this information will appear in the IRIS profile or PPRTV assessment.

FIGURE 3
GUIDANCE ON ASSESSING RISK FROM EARLY-LIFE EXPOSURES FOR CHEMICALS ACTING BY A MUTAGENIC MODE OF ACTION FOR CARCINOGENICITY

If a chemical has been determined to cause cancer by a mutagenic MOA, it is possible that exposures to that chemical in early-life may result in higher lifetime cancer risks than a comparable duration adult exposure.

In risk assessments of exposure to chemicals for which a mutagenic MOA for carcinogenicity has been determined by EPA and a linear low-dose extrapolation performed, one of the following generally pertains:

1) If chemical-specific data on susceptibility from early-life exposures were available for derivation of CSFs, those slope factors are used for risk characterization, and Age Dependent Adjustment Factors (ADAFs) are not applied.
2) If chemical-specific data on susceptibility from early-life exposures were not available, the ADAFs are applied in calculating or estimating risks associated with early-life exposures (USEPA, 2005c).

If the latter case applies, the *Supplemental Guidance for Assessing Susceptibility from Early-Life Exposure to Carcinogens* (USEPA, 2005b) recommends the following default ADAFs be applied in risk assessments:

- 10-fold adjustment for exposures during the first 2 years of life;
- 3-fold adjustment for exposures from ages 2 to <16 years of age; and
- No adjustment for exposures after turning 16 years of age.

In such cases, Equation 11 can be altered to include the ADAFs in the following way:

$$\text{Risk} = (\text{IUR} \times \text{EC}_{<2} \times \text{ADAF}_{<2}) + (\text{IUR} \times \text{EC}_{2\text{-}16} \times \text{ADAF}_{2\text{-}16}) + (\text{IUR} \times \text{EC}_{>16})$$

Sources: USEPA, 2005b and USEPA, 2005c.
Note: All communications and factsheets pertaining to the implementation of the 2005 *Cancer Guidelines* can be found at www.epa.gov/osa/spc/cancer_guidelines.htm.

REC 5277

TR 1962

5.2 Hazard Quotients

The HQ for the inhalation pathway can be calculated with the following general equation:

HQ = EC/(Toxicity Value[1] x 1000 µg/mg) **(Equation 12)**

Where: HQ (unitless) = Hazard Quotient;
EC ($\mu g/m^3$) = exposure concentration (See Equations 7 or 8);
Toxicity Value (mg/m^3) = Inhalation toxicity value (e.g., RfC) that is appropriate for the exposure scenario (acute, subchronic, or chronic).

[1] Risk assessors should refer to the flowchart (Figure 2) to select an appropriate inhalation toxicity value for the exposure scenario at a site in order to calculate the HQ.

6. EXAMPLE EXPOSURE SCENARIOS

This section of the guidance includes examples of the types of exposure scenarios risk assessors may encounter when evaluating inhalation exposures at waste sites. Each scenario includes sample values for exposure parameters and reviews the process of estimating the EC and risks for cancer and other health effects. These examples are provided for illustrative purposes only and are not representative of every exposure scenario that could be encountered at a site. Furthermore, risk assessors should use site-specific values for exposure parameters if practicable when estimating ECs and risk levels or HQs. This would typically require some information on activity patterns for the specific site or the use of professional judgment. If default values are to be used for certain exposure parameters, please consult the Superfund website for up-to-date information on Superfund-recommended default exposure parameters.[34]

6.1 Residential Receptor

An example of a residential scenario could consist of inhalation exposure for up to 24 hours per day, up to 350 days per year for 6 to 30 years. When estimating cancer risk for this type of scenario, Equation 6 is recommended to calculate an EC and Equation 11 is recommended to estimate risk. For estimating hazard quotients for cancer or non-cancer effects, this scenario can be evaluated using the steps outlined in Figure 2. The duration of this scenario ranges from 6 to 30 years, which can be considered chronic (because it consists of repeated exposures for approximately 10 percent of a receptor's lifespan). The frequency of this scenario is generally as frequent as a chronic toxicity test and therefore Equation 8 is recommended to derive a chronic EC and Equation 12 with a chronic toxicity value is recommended to calculate an HQ. If information about multiple MEs is available, risk assessors should proceed according to Section 3.4 to estimate ECs to use in estimating cancer risks or HQs.

When assessing the risk under the residential scenario for children, the risk assessor should keep in mind that exposure parameters, specifically those related to activity patterns (e.g., exposure time, frequency, and duration) may be different for children and adults at the same site. For example, due

[34] http://www.epa.gov/oswer/riskassessment/superfund_hh_exposure.htm.

to outdoor play patterns, children may spend more time near the source of contamination than adults, and thus would have higher exposure time and/or exposure frequency values than adults living in the same location.[35] For indoor vapor intrusion from the subsurface, very young children might be more highly exposed due to substantial time spent indoors.

Beyond the consideration of activity patterns, MEs, and chemicals with a mutagenic MOA for carcinogenicity (as described in Section 5.1), no additional adjustments to account for specific child receptors should be made to the default values. Appendix A of this document is intended to illustrate that the use of default values sufficiently covers age-related variation in DAF or HEC values derived using the EPA *Inhalation Dosimetry Methodology's* default approach.

6.2 Commercial-Industrial/Occupational Receptor

An example of a commercial-industrial or occupational inhalation exposure scenario could be characterized by full-time workers (e.g., 8 hours per day, 5 days per week) in an indoor setting, such as an office building, exposed via vapor intrusion of subsurface contamination on a daily basis for 5 to 25 years. When estimating cancer risk for this type of scenario, Equation 6 is recommended to calculate an EC and Equation 11 is recommended to estimate risk. Following the flowchart in Figure 2, the duration and exposure pattern of this scenario would typically be considered chronic. Therefore, Equation 8 is recommended to derive a chronic EC and Equation 12 is recommended (with a chronic RfC) when calculating an HQ for cancer or non-cancer effects. If information about multiple MEs is available, risk assessors should proceed according to Section 3.4 when deriving ECs to use in estimating cancer risks or HQs. Exposure parameters should be adjusted to consider the exposure time, frequency and duration for this scenario, which may differ from a residential scenario. Risk assessors should also use appropriate exposure parameters for outdoor workers who, similar to children, may spend more time near a source of contamination than indoor workers.

6.3 Construction Worker

One example of a construction worker scenario could involve a long-term project (1-2 years) with workers exposed regularly to contaminant vapors and fugitive dust (8 hours per day, 5 days per week). When estimating cancer risk for this type of scenario, Equations 6 and 11 are recommended to calculate an EC and the risk estimate, respectively. Following the flowchart in Figure 2, the duration of this exposure scenario would typically be considered subchronic. In addition, this exposure is generally as frequent as a subchronic toxicity test. Therefore, Equation 8 is recommended to derive a subchronic EC, and Equation 12 is recommended for use with a subchronic toxicity value to calculate the HQ. If information about multiple MEs is available, risk assessors should proceed according to Section 3.4 when deriving ECs to use in estimating cancer risks or HQs.

6.4 Trespasser/Recreational Receptor

An example trespasser/recreational scenario could consist of an exposure of 1 to 2 hours per day, for 100 days per year or less. When estimating cancer risk for this type of scenario, Equations 6 and 11

[35] For additional information about early-lifestage age groups to consider when assessing children's exposure to environmental contaminants, please consult EPA's *Guidance on Selecting Age Groups for Monitoring and Assessing Childhood Exposures to Environmental Contaminants* (EPA, 2005d).

REC 5279

TR 1964

are recommended to calculate an EC and the risk estimate, respectively. Following the steps in Figure 2 for cancer or non-cancer effects characterized by an RfC, each exposure period should be assessed separately because this exposure lasts only one to two hours each day for an average of two days per week. Therefore, Equation 7 is recommended to derive acute ECs for each exposure period. In addition, Equation 12 is recommended for use with an acute toxicity value to calculate HQs for each exposure period.

7. TARGET CONCENTRATIONS FOR SCREENING ANALYSIS OF INHALATION PATHWAYS

For purposes of this guidance, risk-based screening levels are values that may be compared to the contaminant concentration in air to help risk assessors identify potential contaminants of concern. Screening levels can also be calculated for comparison with samples from source media at a site, such as soil. Screening levels are generally not appropriate for use as clean-up levels; they are intended to aid in initial evaluation of contaminants and exposure pathways of concern prior to proceeding with a baseline risk assessment.[36] If contaminant concentrations in air exceed the risk-based screening levels appropriate for the receptor population of interest, risk assessors should gather site-specific information to determine the need for any remedial action. The following sections outline a recommended approach for calculating screening levels in air as well as source media.

7.1 Target Contaminant Concentrations in Air

The equations recommended for estimating ECs and risk (Equations 6 through 12) can be used to calculate target contaminant concentrations in air by following the four steps outlined below in Table 4.[37]

If air samples from a site are found to be below the target concentration, the risk assessor can generally conclude that this pathway does not pose an unacceptable level of risk from the contaminant. If the concentrations are found to exceed the screening levels, the risk assessor should evaluate the inhalation pathway further by gathering additional site-specific data on contaminant levels, site conditions, and receptor characteristics.

7.2 Screening Levels for Other Media

Inhalation risk-based screening levels may also be calculated for media other than air, including soils, tap water, soil gas, and ground water. The soil gas and ground water values may be derived specifically to address concerns about vapor intrusion from subsurface contamination into indoor spaces.

---

[36] EPA regions, states, or other agencies may support unique screening levels for specific purposes that may differ from the method presented in this document. Generally, when using screening levels it is important that risk assessors understand the target risks, toxicity, and exposure assumptions as well as migration-attenuation assumptions on which they are based, and to apply them for their intended use.

[37] Target contaminant concentrations in air calculated according to the procedure outlined in this document are generally protective for direct inhalation exposures. This process should not be used to calculate concentrations in air to be protective of indirect exposures (e.g., ingestion of crops contaminated through air delivery or vapor phase transfer, ingestion of livestock or fish contaminated indirectly through air deposition or vapor phase transfer).

TABLE 4
RECOMMENDED PROCEDURE FOR CALCULATING RISK-BASED SCREENING CONCENTRATIONS FOR CONTAMINANTS IN AIR

	Cancer Risk-Based	Hazard-Based[1]
Step 1: Select Target Levels	Select target cancer risk (e.g., 1 x 10^{-6}).	Select target HQ (e.g., 1).
Step 2: Identify Toxicity Value[2]	Identify inhalation cancer potency value (e.g., IUR). If none exists, proceed with hazard-based screening level calculation.	Identify inhalation reference value (e.g., RfC) to match exposure scenario (acute, subchronic, or chronic). If none exist, proceed with cancer screening level calculation.
Step 3: Calculate CA	Using target cancer risk from Step 1 along with the receptor- and scenario-specific exposure parameter values, calculate CA; the following equation is recommended: CA = (AT x Target Risk)/(IUR x ET x EF x ED)	Using target HQ from Step 1 along with the receptor- and scenario-specific exposure parameter values, calculate CA; the following equation is recommended: CA = (AT x Target HQ x RfC x 1000 µg/mg)/(ET x EF x ED)
Step 4: Select Screening Concentration	Select minimum of predicted cancer risk- and hazard-based values as screening concentrations.[3] Repeat for each receptor/scenario combination of interest.	

[1] Hazard-based screening concentrations are typically derived from reference values such as RfCs. These values may be available for non-cancer effects but may include cancer, if a nonlinear MOA is thought to operate for a chemical.
[2] If no inhalation toxicity value is available for a chemical, contact STSC for further direction on how to proceed.
[3] Screening levels estimated from the equations presented in Step 3 could yield concentrations that exceed the maximum possible vapor concentration for a chemical. In such cases, it may be useful to calculate the maximum possible vapor concentration of the pure contaminant at the temperature of interest, using the following formula: C_{max} = S x H x 10^3 L/m^3, where S = solubility at 25° C (or temperature of interest) and H (unitless) = Henry's Law Constant at 25° C (or temperature of interest). This equation is based on an established relationship (see, for example, Schwartzenbach et al. 1993), that allows the Henry's Law Constant to be estimated as the ratio of a compound's vapor pressure and aqueous solubility for compounds that are slightly to moderately soluble in water. When the dimensionless Henry's Law constant, H, is used, the relationship described above can be used to calculate the vapor concentration of a saturated solution of a given compound, assuming equilibrium between the vapor and aqueous phases.

7.2.1 Soil Screening Levels

When evaluating risk in a source medium, such as soil, it is typically possible to calculate screening levels for that medium that are expected to be protective of inhalation exposures based on the expected transfer of a contaminant from the source medium to the air. Soil Screening Levels (SSLs) can be described as "risk-based soil concentrations derived for individual chemicals of concern from standardized sets of equations. These equations combine EPA chemical toxicity data with parameters defined by assumed future land uses and exposure scenarios, including receptor characteristics and potential exposure pathways" (USEPA, 2002b). These SSLs may be used for screening analyses and may serve as the basis for the development of Preliminary Remediation Goals (PRGs). Refer to the *Soil Screening Guidance* (USEPA, 1996) and the *Supplemental Guidance for Developing Soil Screening Levels for Superfund Sites* (USEPA, 2002b) for recommended equations that can be used to calculate SSLs for volatilization of chemicals from soil to air and for particulate emissions.

7.2.2 Tap Water Screening Values

Contaminated tap water may pose risk by the inhalation route if the contaminants present are volatile. Screening levels can be calculated for tap water that account for inhalation exposures resulting from the household use of water (e.g., showering, laundering, dishwashing). Risk assessors should consult their local EPA regional risk assessor for direction on how to calculate appropriate screening levels for tap water.

7.2.3 Soil Gas or Ground Water Screening Values for Vapor Intrusion

If there is concern at a site about the possibility of migration of vapor-forming chemicals from contaminated soil gas or ground water into the indoor air of overlying buildings ("vapor intrusion"), screening values can be calculated for these media. Risk assessors should first follow the procedure outlined in Section 7.1 and Table 4 to calculate a risk-based target concentration for the contaminant in air.

For the calculation of a soil gas screening-level concentration, the target air concentration is then divided by an assumed screening-level attenuation factor. The attenuation factor (the ratio of indoor air divided by subsurface source concentration) represents the factor by which subsurface vapor concentrations migrating into indoor air spaces are reduced due to a variety of attenuating mechanisms.

For the calculation of a ground water screening-level concentration, the target air concentration is divided by an assumed screening-level attenuation factor, and the resulting soil gas concentration is converted to a corresponding ground water concentration, assuming equilibrium between the aqueous and vapor phases at the water table.

Risk assessors should consult their local EPA regional risk assessor for direction on how to calculate appropriate screening levels for soil gas and ground water when vapor intrusion is an issue at a site.

8. DEVELOPING AGGREGATE AND CUMULATIVE RISK ESTIMATES

EPA's current approach to estimating cumulative risk or hazard at a site from multiple chemicals, set forth in *RAGS, Part A* (USEPA, 1989), is not affected by the *Inhalation Dosimetry Methodology* and therefore is not being updated at this time. In addition, the aggregation of risks and hazards across multiple exposure routes should remain unchanged. The recommended approaches for aggregating risk and hazard estimates are outlined below.

8.1 Estimating Cumulative Risks and Hazards Across Multiple Chemicals

The recommended method for estimating cumulative risk and hazard at a site from exposure to multiple chemicals is described in *RAGS, Part A*, Section 8.2.2. This method is based on the default approaches described in *Guidelines for the Health Risk Assessment of Chemical Mixtures* (USEPA, 1986). Additional information on this method was subsequently published in the *Supplementary Guidance for Conducting Health Risk Assessment of Chemical Mixtures* (USEPA, 2000b). The recommended methods to use with quantitative cancer risk estimates as well as with HQs are outlined below.

8.1.1 Cancer Risks

When evaluating predicted cancer risks from multiple contaminants, risk assessors should estimate the cancer risk for each substance and then sum these risks. This yields an estimate of total cancer risk, which represents the cumulative predicted cancer risk for the chemicals at a site.

Risk assessors should note, however, that this recommended method assumes "independence of action by the compounds involved (i.e., that there are no synergistic or antagonistic chemical interactions and that all chemicals produce the same effect, i.e., cancer)" (USEPA, 1989). In addition, this simple additive approach is generally most appropriate for total cancer risks less than 0.1. If these assumptions are incorrect, over- or under-estimation of actual multiple-substance risk could result (USEPA, 1989).

8.1.2 Hazard Quotients

When the evaluation involves multiple chemicals assessed via HQs, risk assessors typically first calculate the HQ for each substance, and then sum the individual HQ values. This generally yields an estimated hazard index (HI) for the multiple chemicals assessed via a hazard-based approach. Separate HIs should be calculated for each type of exposure period (i.e., chronic, subchronic, acute). If an HI is greater than 1, it is generally appropriate to derive separate HIs for each target organ of concern (for more information, see *RAGS, Part A*, page 8-14).[38] When multiple acute exposures are present at a site, risk assessors should evaluate each acute exposure event separately. Hazards from multiple chemicals generally should be summed only when the exposures to these chemicals occur simultaneously.[39]

8.2 Aggregating Risk and Hazard Quotients Across Exposure Routes

Guidance for combining the multi-chemical risk estimates and hazard quotients across exposure pathways is described in *RAGS, Part A*, Section 8.3 (USEPA, 1989). In order to determine whether risks or HIs should be combined across exposure pathways, risk assessors should first identify reasonable exposure pathway combinations. Then, risk assessors should examine whether it is likely that the same individuals would consistently face the reasonable maximum exposure (RME) by more than one pathway.

---

[38] This recommended method assumes that "the dose for each individual component is at a level at which effects are not expected to occur, be observable, or be of concern; however, when the doses are combined, effects of concern may be expected or observed in response to the higher dose level of the mixture" (EPA, 2000b, page 12). Another assumption of the HI approach is that the compounds induce the same effect by the same mechanism of action. Therefore, "application of the HI equation to a number of compounds that are not expected to induce the same type of effects or that do not act by the same mechanism, although appropriate as a screening-level approach, could overestimate the potential for effects" (EPA, 1989, page 8-14). This is generally less of a concern if one to two substances are responsible for driving the HI above 1.

[39] In cases where a single chemical is present at a site and receptors are exposed through a series of acute exposure events, the highest single EC should be compared to an acute reference value of the appropriate duration to assess hazard.

The recommended approach for estimating excess cancer risk from exposure via multiple routes is to first estimate cancer risk from each exposure pathway and then sum across the multiple routes.[40]

For the effects assessed via a reference value, risk assessors should calculate the HI for each exposure pathway and sum across the multiple routes. Separate total HIs should be calculated for each type of exposure period (i.e., chronic, subchronic or acute). If the HI exceeds one, there may be concern for potential adverse effects and risk assessors should consider deriving separate HIs for each target organ of concern.

9. RISK CHARACTERIZATION

Risk characterization is the final, summarizing step in conducting a risk assessment. Generally, the purpose of the risk characterization section of a report is to:[41]

- Describe the key findings of the risk assessment in a transparent manner, including identifying hazard, characterizing the dose-response relationship, and describing receptor exposures;
- Identify and describe the scientific and policy assumptions used in the assessment;
- Characterize uncertainties in results; and
- Provide an overall conclusion about the risks present at a site (USEPA, 2000c).

A well-crafted risk characterization section puts risk calculations into context for risk managers so that they may effectively weigh and interpret risk assessment results (i.e., it is the interface between risk assessment and risk management). A few of the key issues and uncertainties involved in calculating risks from inhalation exposures are outlined below.

9.1 Highly Exposed or Susceptible Populations and Life Stages

EPA recommends that the risk characterization portion of the risk assessment explain any particular susceptibilities to inhaled toxicants or potential for increased inhalation exposures among the various receptor groups at a site.[42] We discuss below two possible examples, children and worker receptors, though this discussion could apply to other receptor characteristics as well (e.g., age, disease, gender, genetic characteristics).

9.1.1 Children

One population group that could potentially be more highly exposed to inhalation exposures at a site is children. As discussed in Section 6.2, exposure parameters related to activity patterns (e.g., exposure time, frequency, and duration) and MEs, may vary across age groups. For example, due to outdoor play patterns, children may spend more time near the source of contamination than adults,

---

[40] Note that this approach is generally most appropriate for total cancer risks of less than 0.1 (EPA, 1989).

[41] For specific information on the format of risk characterizations, refer to *Elements to Consider when Drafting EPA Risk Characterizations* (EPA, 1995c).

[42] EPA's IRIS glossary defines susceptibility as the following: "Increased likelihood of an adverse effect, often discussed in terms of relationship to a factor that can be used to describe a human subpopulation (e.g., life stage, demographic feature, or genetic characteristic)" (EPA, 2008b).

and thus would have higher exposure time and/or exposure frequency values than adults living in the same location. Therefore, it is important to carefully describe site-specific exposures to children, and assumptions made in risk calculations.[43]

If chemical-specific data on susceptibility to the toxic effects from early life exposures are available, these data are considered when developing toxicity values that specifically address differential toxicity to the young (e.g., vinyl chloride) (USEPA, 2005c). Toxicity values derived using the default approach from the *Inhalation Dosimetry Methodology* are developed for the human population as a whole, including sensitive subgroups. Therefore, as described in Section 6 of Appendix A, no quantitative adjustment of toxicity values derived using the default approach in the *Inhalation Dosimetry Methodology* is recommended for specific age groups to account for different ventilation rates or body weights of specific age groups.

When evaluating risk to carcinogenic chemicals with a demonstrated mutagenic MOA but which lack chemical-specific information on susceptibility from early life exposures, EPA recommends a quantitative adjustment of the toxicity value to account for early life susceptibility, as described in the *Supplemental Cancer Guidelines* (see USEPA, 2005b & 2005c; and Section 5.1 of this guidance for further information).

9.1.2 Workers

Workers could have increased exposure under certain occupational scenarios. Some outdoor workers might spend more time near a source of contamination in the course of their job and this should be reflected in adjustments to the exposure parameters (e.g., ET, Exposure Frequency (EF), and ED) describing the worker exposure scenario. Toxicity values derived using the *Inhalation Dosimetry Methodology* are developed for the human population as a whole, including sensitive populations and life stages. In the default *Inhalation Dosimetry Methodology* approach, typical variation in IRs between periods of high activity and rest is considered. However, if workers have especially high levels of exertion with correspondingly high ventilation rates, these workers could be at the upper end of the risk range, particularly if they are exposed to Category 1 gases, which have direct effects in the respiratory tract. This implication should be recognized in the risk characterization section.

9.2 Uncertainties in Inhalation Risk Assessment

This guidance recommends including an assessment of the key uncertainties that may significantly impact risk estimates for inhaled chemicals. This should ensure transparency, clarity, reasonableness and consistency in risk assessments, as recommended by EPA's *Policy for Risk Characterization* (USEPA, 1995a). Other sources of uncertainty may be present and other EPA documents provide guidance on characterizing uncertainty in risk the assessment process (USEPA, 1992, 1995a, 1995b, 1995c, 1997a, 1997b). Key uncertainties related to inhalation risk assessment, which is the focus of this section, include the development of ECs, choice of toxicity value, lack of quantitative toxicity information via inhalation, and the approach to estimating and aggregating risks. According to EPA's *Guidance for Risk Characterization*, the discussion of uncertainty "should reflect the type and complexity of the risk assessment, with the level of effort for analysis and discussion of uncertainty

[43] For additional information on children's health risk assessment, please consult *A Framework for Assessing Health Risks of Environmental Exposures to Children* (EPA, 2006b).

REC 5285

TR 1970

corresponding to the level of effort for the assessment" (USEPA, 1995b). Therefore, risk assessors should provide a qualitative and/or quantitative evaluation of key uncertainties pertaining to inhalation risk, and their impact on the outcome of the assessment, consistent with the level of effort of the specific risk assessment.

9.2.1 Development of Exposure Concentrations

As described in Section 3 of this guidance, with the exception of acute exposures, time-weighted averages are typically used to represent intermittent or variable inhalation exposures to receptors at a site. This recommended approach is consistent with the duration adjustment approach (based on Haber's Law) that is generally used in deriving the toxicity values (see Section 2.1.1.1 for further information). As mentioned in Section 3, when evaluating situations in which the exposure is long-term, yet there are short periods of significantly higher exposure, those periods should also be assessed using appropriate short-term toxicity values. This ensures that periods of much higher exposure can be appropriately assessed and not "diluted out" in the assessment of longer-term exposure.

When information on multiple MEs exists at a site, risk assessors may choose to estimate ECs as outlined in Section 3.4. However, this typically requires sufficient time-activity information of receptors at a site to accurately determine the time spent in each ME. Incomplete or low quality data on time-activity pattern may introduce uncertainty into the estimation of the ECs for MEs. Risk assessors should describe the quality and completeness of these data.

The recommended method for determining the CA at a site can potentially introduce uncertainty into the EC calculations. For instance, if contaminant concentrations in air are measured, risk assessors should consider uncertainties related to how well the set of air samples available at a site represents the duration and time period being assessed as well as measurement uncertainty related to the methods and equipment used. In addition, risk assessors should describe any potential confounding of indoor air samples by other sources of contaminants (e.g., household products). If contaminant concentrations in air are modeled, (e.g., by EPA's spreadsheet models for vapor intrusion) risk assessors should address model-related uncertainties and their potential impact on the estimate of contaminant concentrations in air. Considerations of particle size at the site versus particle size used to derive the toxicity value are also important.

9.2.2 Toxicity Assessment

Section 4.1 of this document indicates that some IURs on IRIS were developed through extrapolation from oral CSFs (see Appendix B of this document). The use of toxicity values derived through simple route-to-route extrapolation introduces additional uncertainty into risk calculations. Therefore, risk assessors should indicate when extrapolated IURs are used and should characterize the potential impact of the uncertainty associated with using these values, if known.

Section 4.2 and Appendix C of this guidance recommends contacting STSC to help identify appropriate toxicity values for conducting a risk assessment at Superfund sites in the absence of published inhalation toxicity values. If STSC is unable to recommend a toxicity value, risk assessors should acknowledge the resulting uncertainty in risk associated with the chemical(s) lacking inhalation toxicity data. If STSC provides risk assessors with a toxicity value based on a PBPK

model, model uncertainty should be discussed. In addition, if STSC provides risk assessors with one or more structurally analogous chemicals, risk assessors can use toxicity data for these chemicals to help characterize the potential magnitude of the inhalation risk associated with the chemical(s) lacking data. In this case, risk assessors should acknowledge the uncertainty associated with relying on toxicity data for analogous chemicals to characterize risk at the site.

Risk assessors should also acknowledge chemicals that lack duration-appropriate toxicity values and discuss the potential impacts of substituting alternative toxicity values for HQ calculations. For instance, if the ED is determined to be subchronic but no subchronic inhalation RfC or analogous toxicity value is available for that chemical, the risk assessor should address the uncertainty associated with calculating an HQ using a toxicity value for a different duration, such as chronic, or the impact of not quantifying those risks. In addition, if risk assessors use an acute toxicity value that does not match the duration of the acute exposure being assessed, the possibility of under or overestimating hazard should be discussed.

When conducting a screening-level risk assessment using screening values such as those described in Section 7, it is important to further evaluate and clearly describe the quality and uncertainties associated with the inhalation toxicity values used in the risk assessment if measured sample contaminant concentrations at a site exceed these screening values.

9.2.3 Estimating Cancer Risks

For high exposures, for example those within the range of epidemiological studies (usually those predicted to have risks greater than 10^{-2}), the IUR derived from the linear extrapolation below the range of observation is generally not appropriate for use (see Section 5.1 of this document for further information).[44] Risk assessors should provide specific information in the risk characterization describing how these high exposures were addressed in the risk assessment. For instance, if a risk assessor chose to provide a semi-quantitative approach (e.g., indicating that risks are above 10^{-2}), this should be indicated, along with a description of the uncertainties involved in not fully quantifying risk associated with exposure to this chemical. If a risk assessor chose to use the original model in the IRIS file or other technical background document, the risk characterization section should include a description of any uncertainties in the model used and could contain examples of the risks estimated.

9.2.4 Estimating Risk and Hazard from Multiple Chemicals and Exposure Pathways

Risk assessors should also describe uncertainties involved in aggregating risk and hazard across multiple chemicals and exposure pathways. For instance, the approaches described in Section 8 of this document are associated with several assumptions (e.g., independence of action and doses for individual compounds at levels not expected to be of concern). If these assumptions are not met, aggregation may not be appropriate. This should be fully described in the risk characterization section and any uncertainties involved in the lack of quantitative information should be indicated.

[44] Also refer to Section 8.2.1 of *RAGS, Part A* for further discussion of this topic (EPA, 1989, page 8-6).

APPENDIX A

ANALYSIS OF DEFAULT APPROACH FOR HEC DERIVATION AS COMPARED TO POPULATION- AND LIFESTAGE-SPECIFIC CALCULATIONS

NOTE: The Agency's inhalation dosimetry methodology (USEPA, 1994; hereafter, "the *Inhalation Dosimetry Methodology*") is a technical report that describes the derivation of human equivalent concentrations (HECs) from animal (or human) studies, as well as the other steps involved in developing a chronic Reference Concentration (RfC). This appendix is included to illustrate the HEC derivation using the *Inhalation Dosimetry Methodology*'s default approach (with the recommended default values for humans), and to also illustrate the impact of substituting alternate age- and activity-specific human values into the default calculations. The default approach is employed for chemicals for which more chemical-specific dosimetric and pharmacokinetic data are not available, thus precluding the use of more advanced models for deriving the HEC. The calculations in this appendix do not represent a refined or optimal model for assessing intra-human variability (e.g., age- and activity-specific risks), and are not intended to imply that risk assessors should deviate from the *Inhalation Dosimetry Methodology* by substituting alternate values into the default calculations. Age-specific data are limited. Because of these limitations, the calculations made for different ages and exposure groups in this appendix are not recommended for use in quantitative risk assessment (i.e., they are only for the purpose of illustration), but may be useful in discussions of uncertainty and variability associated with the default approach.

It is also noted that, as of this writing, the Agency is involved in a routine reevaluation of scientific advancements in the field, with consideration of the need for improvement to the *Inhalation Dosimetry Methodology*. Any revisions will consider current understanding of inhalation dosimetry and differences across and within species, as well as the Agency's risk assessment needs. In order to transparently and quantitatively address children's inhalation dosimetry and risk assessment, this guidance document will be updated (on-line) when Agency methodology updates are available that are specific to early life. Until that time, the 1994 *Inhalation Dosimetry Methodology* is the appropriate Agency methodology.

INTRODUCTION

This appendix consists of examples and discussions illustrating the current default chemical category-specific approach to inhalation dosimetry for the various categories of gases and particles as described in *Methods for Derivation of Inhalation Reference Concentrations and Application of Inhalation Dosimetry* (USEPA, 1994; hereafter, the *Inhalation Dosimetry Methodology*). This default inhalation dosimetry approach is used to convert toxicological and epidemiological study data to an HEC that can then be used to derive chronic RfCs for the human population (inclusive of susceptible populations and life stages, such as children) and also in the development of Inhalation Unit Risks (IURs) (USEPA, 2005). The default approach does not rely on age- or activity-specific values for physiological parameters when calculating HECs; however the default approach has been designed by EPA to derive reference values that are protective across the entire population.

The appendix includes six sections. Sections 1 through 3 address Category 1 gases. These sections provide example calculations for Category 1 highly reactive, high water solubility gases that are typically absorbed in the upper airways, exhibiting adverse effects in the extrathoracic (ETh), tracheobronchial (TB), and pulmonary (PU) regions of the respiratory tract, respectively. These examples include comparisons of HEC calculations based on default parameters with those derived using age- and activity-specific parameters for the respiratory region affected. Section 4 addresses Category 3 low reactivity, limited water solubility gases that exhibit systemic effects outside the respiratory tract. Section 5 addresses changes in particle deposition in the respiratory tract across age groups. The conclusions are summarized in Section 6.

When reviewing the examples, please note the following:

- An RfC derived using the *Inhalation Dosimetry Methodology* is defined as "an estimate (with uncertainty spanning perhaps an order of magnitude) of a continuous inhalation exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime" (USEPA, 2008).

- All examples in this appendix are based on the *Inhalation Dosimetry Methodology*. EPA is committed to periodically reviewing and updating the *Inhalation Dosimetry Methodology* to ensure that it reflects the current state of the science and that it yields toxicity values that sufficiently cover potential age- and activity-related variation in inhalation exposure. A review and update is currently underway.

- The examples in this appendix are all based on calculating HECs from a point of departure (POD) for non-cancer effects (e.g., a No Observed Adverse Effect Level (NOAEL), Lowest Observed Adverse Effect Level (LOAEL), or Benchmark Concentration, Lower confidence limit (BMCL)). These calculations could also be performed in an identical manner for carcinogens using a POD for cancer risk estimate derivation (e.g., a Lower limit on the Effective Concentration (LEC) value).

- The default animal and human values for minute volume (V_e) and surface area (SA) used in these examples were obtained from *Methods for Derivation of Inhalation Reference Concentrations and Application of Inhalation Dosimetry* (USEPA, 1994).[45] The age- and activity-specific V_e values were obtained from the International Commission on Radiological Protection (ICRP) Publication 66, *Human Respiratory Tract Model for Radiological Protection* (ICRP, 1994).[46] Age-specific SA values used in Examples 1 and 2 were calculated using scaled estimates for the mass and thickness of respiratory region-specific target tissue from ICRP (1994); Values for Example 3 were calculated from an allometric scaling equation presented in a publication by Zeltner et al. (1987). EPA's Office of Research and Development (ORD) selected these data following review of the available physiological data for the age groups indicated in the examples.

- Chemical-specific data from the Integrated Risk Information System (IRIS) file for acrolein were used in the ETh example (Example 1). However, the other two examples, which focus on effects in the TB and PU regions, respectively, use hypothetical data for the POD because there are currently no chemicals on IRIS exhibiting Critical Effects (for RfC derivation) in those regions.[47] The conclusions of these two examples are unaffected by the use of hypothetical data because the results are driven by the values of parameters that are not chemical-specific (i.e., SA and V_e).

---

[45] The minute volume is the total ventilation per minute and equals the product of the tidal volume (the air volume entering or leaving the lungs with a single breath) and the respiratory frequency.

[46] For further information on inhalation rates in humans under different scenarios, refer to Chapter 5 of EPA's *Exposure Factors Handbook* (EPA, 1997).

[47] Hypothetical examples for the TB and PU regions were included in this appendix because currently no RfCs for gases on IRIS are calculated based on animal studies showing health effects occurring in these regions of the respiratory system

1. EXAMPLE 1: CATEGORY 1 GAS, EXTRATHORACIC EFFECTS, ACROLEIN

The Dosimetric Adjustment Factor (DAF) for a Category 1 gases, the Regional Gas Dose Ratio (RGDR), is based on the animal to human ratio of the V_e divided by the SA of the region of the respiratory tract where the effect occurs. For acrolein, the effect occurs in the ETh region. The DAF is typically calculated using the following equation (USEPA, 1994, Equation 4-18):

$$RGDR_{ETh} = \frac{\left(\frac{V_e}{SA_{ETh}}\right)_{animal}}{\left(\frac{V_e}{SA_{ETh}}\right)_{human}} = \frac{\frac{0.14\,L/min}{15\,cm^2}}{\frac{13.8\,L/min}{200\,cm^2}} = 0.14 \qquad \textbf{(Equation A-1)}$$

The default *Inhalation Dosimetry Methodology*-recommended values for the V_e and SA_{ETh} of the Wistar rat (the animal in the principal study for acrolein) are 0.14 L/min (0.20 m^3/day) and 15 cm^2, respectively (USEPA, 1994). EPA's default human values are 13.8 L/min (20 m^3/day) for V_e and 200 cm^2 for SA_{ETh} (USEPA, 1994). The RGDR for the ETh region ($RGDR_{ETh}$) was calculated using these values for the rat and the human as shown in Equation A-1. In the laboratory animal study on acrolein, the LOAEL adjusted for continuous exposure ($LOAEL_{[ADJ]}$) of 0.16 mg/m^3 (USEPA, 2003) is used as the point of departure. The $LOAEL_{[HEC]}$ is the $LOAEL_{[ADJ]}$ multiplied by the $RGDR_{ETh}$.

To illustrate any potential age- or activity-related variation in the $LOAEL_{[HEC]}$ that might result from using human parameter values other than the defaults, scaled estimates for the mass and thickness of ETh target tissue from ICRP (1994) at different ages are used to calculate the SA_{ETh} values in Table A-1. Age- and activity-related V_e reported in ICRP (1994) are based on daily time-budgeted reference values. Table A-1 shows little variation in the resultant $LOAEL_{[HEC]}$ across the groups in this example. The default procedure produces the lowest $LOAEL_{[HEC]}$ value in Table A-1 and is, therefore, sufficient to cover all of these groups.

TABLE A-1
COMPARISON OF THE HEC-DEFAULT (EPA, 1994) WITH EXAMPLE $LOAEL_{[HEC]}$ VALUES FOR HUMANS OF DIFFERENT AGES AND ACTIVITY PATTERNS FOR THE EXTRATHORACIC REGION

	Total $V_{e\ (human)}$ (L/min)[a]	$SA_{ETh\ (human)}$ (cm^2)[b]	$(V_e/SA_{ETh})_{human}$ (L/min-cm^2)	$RGDR_{ETh}$	$LOAEL_{[HEC]}$ (mg/m^3)
Outdoor Worker, Male	17.5	470	0.037	0.25	0.04
Sedentary Worker, Male	15.4	470	0.033	0.28	0.04
Sedentary Worker, Female	12.6	407	0.031	0.30	0.05
15 Year-Old Male	14.0	439	0.032	0.29	0.05
15 Year-Old Female	10.9	397	0.027	0.35	0.06
10 Year-Old	10.6	293	0.036	0.26	0.04

HEC - Default	13.8	200	0.069	0.14	0.02

[a] These values are from the ICRP publication, Tables 8, 27, B.16a, B.16b and B.17 (ICRP, 1994).
[b] These values are from the ICRP publication, Tables 1 and 5 (ICRP, 1994).

2. EXAMPLE 2: CATEGORY 1 GAS, TRACHEOBRONCHIAL EFFECTS, HYPOTHETICAL CHEMICAL

The DAF for a Category 1 gas or vapor exhibiting effects in the TB region is based on the animal to human ratio of the V_e divided by the SA of the TB region for each species. The DAF is typically calculated using the following equation:

$$RGDR_{TB} = \frac{\left(\frac{V_e}{SA_{TB}}\right)_{animal}}{\left(\frac{V_e}{SA_{TB}}\right)_{human}} = \frac{\frac{0.14\ L/min}{22.5\ cm^2}}{\frac{13.8\ L/min}{3200\ cm^2}} = 1.4 \qquad \textbf{(Equation A-2)}^{48}$$

This example assumes that the hypothetical chemical has been tested on Wistar rats and therefore utilizes the EPA animal default values for that strain. The V_e value used is 0.14 L/min (0.20 m^3/day) and the default SA_{TB} is 22.5 cm^2 (USEPA, 1994). EPA's default human values are 13.8 L/min (20 m^3/day) for V_e and 3200 cm^2 for SA_{TB} (USEPA, 1994). The RGDR for the TB region ($RGDR_{TB}$) is calculated using these values for the rat and the human, as shown in Equation A-2. The example also assumes a NOAEL adjusted for continuous exposure ($NOAEL_{[ADJ]}$) of 0.16 mg/m^3 as the point of departure. The $NOAEL_{[HEC]}$ is the $NOAEL_{[ADJ]}$ multiplied by the $RGDR_{TB}$.

Table A-2 shows little variation across age and activity groups in the $NOAEL_{[HEC]}$. The variation from the default (less than a factor of 2) is less than the default value of 10 used for the uncertainty factor for intraspecies variability when deriving the RfC. Application of the normal procedure for

[48] This equation is the reduced, default version of Equation 4-19 of the *Inhalation Dosimetry Methodology*. Equation 4-19 is reduced to this form consistent with the derivation of the reduced form of the RGDR equation of extrathoracic effects described in section 4.3.6.1 and Appendix I of the *Inhalation Dosimetry Methodology*.

determining the RfC will accommodate the observed variation. In addition, RfCs and IURs are developed for chronic exposure and will generally involve an exposure for multiple years.

TABLE A-2
COMPARISON OF THE HEC-DEFAULT (EPA, 1994) WITH EXAMPLE $LOAEL_{[HEC]}$ VALUES FOR HUMANS OF DIFFERENT AGES AND ACTIVITY PATTERNS FOR THE TRACHEOBRONCHIAL REGION

	Total $V_{e\,(human)}$ (L/min)[a]	$SA_{TB\,(human)}$ (cm^2)[b]	$(V_e/SA_{TB})_{human}$ (L/min-cm^2)	$RGDR_{TB}$	$NOAEL_{[HEC]}$ (mg/m^3)
Outdoor Worker M	17.5	2660	0.0066	0.94	0.15
Sedentary Worker M	15.4	2660	0.0058	1.1	0.18
Sedentary Worker F	12.6	2640	0.0048	1.3	0.21

3 Months	2.0	712	0.0028	2.2	0.35
HEC-default	13.8	3200	0.0043	1.4	0.22

[a] These values are from the ICRP publication, Tables 8, 27, B.16a, B.16b and B.17 (ICRP, 1994).
[b] These values are from the ICRP publication, Tables 1 and 5 (ICRP, 1994).

3. EXAMPLE 3: CATEGORY 1 GAS, PULMONARY EFFECTS, HYPOTHETICAL CHEMICAL

The DAF for a Category 1 gas or vapor with an effect in the PU region is based on the animal to human ratio of the alveolar ventilation rate (Q-alv) divided by the SA of the PU region (SA_{PU}) for each species. The Q-alv is approximately equal to the V_e multiplied by 0.7. This adjustment accounts for the anatomic/physiologic deadspace in the PU region, making the Q-alv equivalent to the amount of inspired air available for gas exchange (West, 2000). The DAF for this region of the respiratory tract is typically calculated using the following equation:

$$RGDR_{PU} = \frac{\left(\frac{Q-alv}{SA_{PU}}\right)_{animal}}{\left(\frac{Q-alv}{SA_{PU}}\right)_{human}} = \frac{\frac{0.1\,L/min}{0.34\,m^2}}{\frac{9.7\,L/min}{54\,m^2}} = 1.6 \qquad \textbf{(Equation A-3)}^{49}$$

This example assumes that the hypothetical chemical has been tested on Wistar rats and therefore utilizes the EPA animal default values for that strain. The V_e valued used is 0.14 L/min (0.20 m^3/day), which when multiplied by 0.7, yields a Q-alv of 0.1 L/min. The example uses the EPA default rat SA_{PU} of 0.34 m^2 (USEPA, 1994). EPA's default human values are 13.8 L/min (20

[49] This equation is the reduced, default version of Equation 4-23 of the *Inhalation Dosimetry Methodology*. Equation 4-23 is reduced to this form consistent with the derivation of the reduced form of the RGDR equation of extrathoracic effects described in section 4.3.6.1 and Appendix I of the *Inhalation Dosimetry Methodology*.

m^3/day) for V_e (which yields a Q-alv of 9.7 L/min) and 54 m^2 for SA_{PU} (USEPA, 1994). The RGDR for the PU region ($RGDR_{PU}$) is calculated using these values for the rat and the human, as shown in Equation A-3. The example also assumes a $NOAEL_{[ADJ]}$ of 0.16 mg/m^3 as the point of departure. The $NOAEL_{[HEC]}$ is the $NOAEL_{[ADJ]}$ multiplied by the $RGDR_{PU}$.

Table A-3 below provides the Q-alv values for humans based on the daily time-budgeted V_e for different ages and activity levels from the ICRP publication (1994). SA data for the PU region in the ICRP publication are estimated using an allometric scaling model fitted to data from a morphometric analysis of SA_{PU} in a sample of seven children (ranging in age from 26 days to 5 years) and eight adults (Zeltner et al., 1987). ORD selected the Zeltner analysis for this example because these SA_{PU} data are based on empirical morphometric measurements of human lungs as opposed to scaled estimates determined from lung models (such as those done by Yu and Xu, 1987 or Yu and Yoon, 1991). In addition, the children and adult SA_{PU} values calculated in the Zeltner analysis are supported by several independent studies that measured SA_{PU} in children (Langston et al., 1984) or in adults using similar morphometric techniques (Crapo et al., 1982 & 1983; Stone et al., 1992; Mercer et al., 1994).

Table A-3 shows little variation in the resultant $NOAEL_{[HEC]}$ across the groups in this example. The default procedure produces the lowest $NOAEL_{[HEC]}$ value in Table A-3 and is, therefore, sufficient to cover all of these groups.

TABLE A-3

COMPARISON OF THE HEC-DEFAULT (EPA, 1994) WITH EXAMPLE $LOAEL_{[HEC]}$ VALUES FOR HUMANS OF DIFFERENT AGES AND ACTIVITY PATTERNS FOR THE PULMONARY REGION

	Total V_e (L/min)[a]	Q-$alv_{(human)}$ (L/min)[b]	$SA_{PU\ (human)}$ (m^2)	$(Q\text{-}alv/SA_{PU})_{human}$ (L/min-m^2)	$RGDR_{PU}$	$NOAEL_{HEC}$ (mg/m^3)

HEC-Default	13.8	9.7	54.0	0.18	1.6	0.26

[a] These values are from the ICRP publication, Tables 8, 27, B.16a, B.16b and B.17 (ICRP, 1994).
[b] These values are from Zeltner et al. (1987).

4. CATEGORY 3 GASES

The DAF for a Category 3 gas or vapor is based on the ratio of the animal blood:gas partition coefficient to the human blood:gas partition coefficient and is typically calculated using the following equation:

$$DAF = \frac{(H_{b/g})_{animal}}{(H_{b/g})_{human}} \qquad \textbf{(Equation A-4)}$$

The blood:gas partition coefficient is primarily determined by the solubility of the gas in an aqueous medium as well as the protein and lipid content of the blood. There is little reason to suspect that the blood:gas partition coefficient for a non-metabolized chemical will vary greatly across the human population. The limited data available indicate no difference in the blood:gas partition coefficient with age for methylene chloride in mice (Thomas et al., 1996), and for sevoflurane, isoflurane, and halothane in humans (Malviya and Lerman, 1990). Two studies examining the solubility of volatile anesthetics (isoflurane, enflurane, halothane, and methoxyflurane) in the blood and body tissues found higher blood:gas partition coefficients in adults compared with children (Lerman, et al., 1984 & 1986). Any variability in the blood:gas partition coefficient with age is expected to be less than the default value of 10 used for the uncertainty factor for intraspecies variability when deriving the RfC. Any variability in the blood:gas partition coefficient with age is also not expected to cause a large overestimate or underestimate in the calculated cancer risk.

Because of the limited data available, the *Inhalation Dosimetry Methodology* makes the science policy decision to use a value of one for the ratio of the partition coefficients when the animal to human ratio exceeds one or when the animal or human value is unknown. At this time, all chemicals on IRIS for which both human and animal data are available have an animal to human ratio of partition coefficient greater than 1.[50] Therefore, the default assumption of one is a conservative approach that is not likely to underestimate the chemical-specific DAF.

5. PARTICLE DEPOSITION ACROSS AGE GROUPS

The DAF for a particle causing an effect in the respiratory tract, the Regional Dose Deposition Ratio ($RDDR_r$), is based on the animal to human ratio of the V_e and the fractional deposition of the particle in that region (F_r), divided by the surface area of the region where the effect occurs (SA_r) (USEPA, 1994). Inherent in this derivation is the assumption that 100 percent of the deposited dose remains in the respiratory tract and any clearance mechanisms are not considered. The $RDDR_r$ is typically calculated using the following equation:

$$RDDR_r = \frac{\left(\frac{V_e}{SA_r} \times F_r\right)_{animal}}{\left(\frac{V_e}{SA_r} \times F_r\right)_{human}} \qquad \textbf{(Equation A-5)}$$

[50] While 1,4-dioxane has not yet been evaluated on IRIS, it provides an exception to this statement, in that the blood:gas partition coefficient is 2750 for mice, 1850 for rats, and 3650 for humans, yielding an animal to human ratio of 0.75 for mice and 0.51 for rats (Reitz et al., 1990).

The DAF for a particle causing an extra-respiratory (ER) effect, the $RDDR_{ER}$, is based on the animal to human ratio of the V_e and the total deposition of the particle in the entire respiratory tract (F_{total}), divided by body weight (BW) (USEPA, 1994). The $RDDR_{ER}$ assumes that 100 percent of the deposited dose in the entire respiratory tract is available for uptake into the systemic circulation. The following general equation can be used to estimate the $RDDR_{ER}$:

$$RDDR_{ER} = \frac{\left(\frac{V_e}{BW} \times F_{total}\right)_{animal}}{\left(\frac{V_e}{BW} \times F_{total}\right)_{human}} \qquad \textbf{(Equation A-6)}$$

The information on particle deposition in various age groups is quite limited. A discussion of the current state of the science can be found in the *Air Quality Criteria for Particulate Matter Volume II*, Section 6.2.3.2 (USEPA, 2004; hereafter, *PM Criteria Document*).

Experimental and modeling results are summarized in Table A-4. The results for experimental studies are mixed, some suggesting higher deposition in children and others finding no difference across age groups. Bennett and Zeman (1998) and Schiller-Scotland et al. (1994) found no difference between total deposition of particles in the respiratory tract of children (aged 7 to14 and 6 to12, respectively) and adults for 1 to 2 micrometer particles. Schiller-Scotland et al. did find two- to three-fold higher total particulate deposition in 6 to 12 year olds for particles of 2 to 3 micrometers in size. In addition, Bennett et al. (1997) found that deposition in the ETh region was 50 percent greater in children than adults. The *PM Criteria Document* concludes that "these...studies ...do not provide unequivocal evidence for significant differences in deposition between adults and children" (USEPA, 2004, page 6-29). The document notes, however, that children may have higher activity levels and higher associated minute ventilation per lung size, potentially causing a greater size-specific dose of particles to the lung.

Modeled results suggest a higher deposition of particles in the TB region of children when compared to adults, depending on the particle size (Xu and Yu (1986); Hofmann et al. (1989); Musante and Martonen (1999); Phalen and Oldham (2001); Asgharian et al. (2004); Jarabek et al. (2005); Ginsberg et al. (2005)). Mixed results again are found in modeling studies for total deposition and deposition in other respiratory regions. In general, where differences are observed in either experimental or modeled studies, variability in deposition between age groups has been reported to be most often in the range of 1- to 3-fold greater for children than for adults, but ranging from equivalency or less up to 7-fold greater.[51]

[51] A modeling analysis examining deposition fraction per unit area at various airway generations of the lung as a function of age for various particle sizes (ranging from 0.01 to 10 μm) reported comparisons between a 3-month old and 21-year old that ranged from equivalency up to a 14-fold difference in this metric for some specific airway generations (Asgharian et al., 2004).

TABLE A-4
PARTICLE DEPOSITION ACROSS AGE GROUPS

Study	Particle Size	Results
Experimental Studies		
Becquemin et al. (1991)	Various	Nasal deposition higher in adults (up to 1.8-fold higher at rest and up to 3.4-fold higher during exercise) than children – meaning that thoracic airways of children are less protected than those of adults.
Bennett et al. (1997)	4.5 µm	-ETh deposition of particles 50 percent greater in children (higher for younger ages). -No significant difference in total respiratory tract deposition.
Bennett and Zeman (1998)	1-2 µm	No difference between 7-14 year olds and adults in total deposition of particles in the respiratory tract.
Schiller-Scotland et al. (1994)	1-2 µm	No difference between 6-12 year olds and adults in total deposition of particles in the respiratory tract.
	2-3 µm	Two- to three-fold higher total deposition of particles in 6-12 year olds versus adults.
Modeled Studies		
Asgharian et al. (2004)	0.01-10 µm	-Up to 1.2-fold higher total deposition in 3 month olds compared to adults in the TB region. -Up to 1.5-fold higher total deposition in 8 year olds compared to adults in the alveolar region. Total deposition higher in adults than 3 and 23 month olds (up to 2-fold). -Estimates of deposition fraction per unit area at various airway generations of the lung and various particle sizes highest for 3 month olds compared to adults (up to 14-fold). Higher deposition also seen for 23 month olds (up to 5-fold) and 8 year olds (up to 3-fold) compared with adults. No difference in deposition in 14 year olds compared to adults.
Cheng et al. (1995)	0.0046-0.2 µm	Nasal casts of children's airways found increased deposition efficiency for ultrafine particles with decreasing age, suggesting that young children may receive a higher dose of ultrafine particles to the upper airways.
Ginsberg et al. (2005)	0.001-10 µm	-Higher deposition in 3 month olds compared with adults for coarse and fine particles in the upper TB (up to 2-fold) and PU (up to 4-fold) regions. -Higher deposition in adults in the lower TB region.
Hoffmann et al. (1989)	1-2 µm	-1.5- to 2-fold higher total deposition in the TB region for particles in resting 8 year olds versus adults. -40-50 percent lower total deposition of particles in 8 year olds under conditions of exercise.
Jarabek et al. (2005)	0.3-6 µm	-Retained mass in the TB region normalized to regional SA was compared across age groups. -Up to 2-fold lower deposition in 3 month olds compared to adults. -Up to 2-fold higher deposition in 3 year olds and 14 year olds compared to adults.
Musante and Martonen (1999)	0.25-5 µm	-Total deposition was generally higher in children (ages 7, 22, 48, and 98 months) than adults (e.g., total lung deposition in 48-month olds was 38 percent higher than adults for 1µm particles). -TB deposition monotonically decreased as a function of age (i.e., younger children had increased TB deposition). -PU deposition greatest in the 48 and 98-month children.
Musante and Martonen (2000)	2 µm	3-fold higher deposition of particles in the PU region for 7 month olds versus adults.
Oldham et al. (1997)	Various	Airway models of trachea and bronchial airways showed total deposition in children (ages 4 and 7) greater than adult (up to approximately 7-fold higher for 4 year olds compared to adults for 4.5 µm particles).
Phalen and Oldham (2001)	0.1-10 µm	-No difference in total deposition of particles in 2 year olds versus adults. -Somewhat higher (13-81 percent; depending on particle size) deposition of particles in the TB region. -Lower deposition of particles in the PU region.
Xu and Yu (1986)	Various	Increased total deposition (up to 1.5-fold higher) in children aged 6 months, 2 years, and 8 years compared with adults for particles of varying sizes.

6. CONCLUSIONS

The examples and discussions included in this appendix suggest that the *Inhalation Dosimetry Methodology's* default approaches for derivation of the HEC for Category 1 gases with effects in the ETh, TB, and PU regions and for Category 3 gases typically are sufficient to cover variation across human age- and activity-level groups. The process for deriving an RfC from the HEC includes applying an uncertainty factor (UF) to account for within-species variability, adding further protection. When deriving an IUR for a carcinogen, UFs are not used. However the procedures for estimating an IUR incorporate conservative assumptions that would likely accommodate the degree of variation observed in these examples.

Experimental and modeling results for particles suggest the potential for small differences in deposition of particles in the respiratory tract as a function of age. The assumption that 100 percent of the deposited dose is available for uptake into the systemic circulation (for remote acting toxicants), or for activity in the respiratory tract (for local toxicity) is likely to result in an overestimation of dose to the target tissue. Any small variation in deposition among age groups should be considered against the potential magnitude of such overestimation. These differences in calculated deposition are small relative to the default 10-fold UF that accounts for intra-species variability in the derivation of the RfC. In addition, RfCs and IURs are developed for chronic exposure and will generally involve an exposure for multiple years. No additional correction of the toxicity values for these age groups is needed when the RfC or IUR is used in a risk assessment. Calculations in these examples are based on empirical data from sources listed and referenced in ICRP Publication 66 (ICRP, 1994). While ORD selected the ICRP values as the best estimates for these examples, other published values for V_e and SA exist. The use of alternate values may change the $LOAEL_{[HEC]}$ calculated for the various populations and life stages and may show more or less variability in results across the age and activity groups. In addition, the examples for the TB and PU regions are based on a hypothetical chemical, since currently no RfCs for gases on IRIS are calculated based on animal studies showing health effects occurring in these regions of the respiratory system. Given the parameter values used in the default method for calculating the HEC, it is likely that the process would yield results sufficient to cover populations and life stages with varying activities and physiologic characteristics.

Note that the available data, albeit limited, generally support these conclusions. As recommended by the Reference Dose (RfD)/RfC Technical Panel (USEPA, 2002), EPA has been exploring issues involving dose to the young from inhalation exposures, both theoretically and experimentally as well as further considering the existing animal-to-human extrapolation procedures described in current methodologies (e.g., USEPA, 1994). This is especially important because of the significant developmental changes that occur in the lung from birth well into adolescence (Pinkerton and Joad, 2000). The review and updating of these methodologies will be based on the best available science.

CHEMICALS ON IRIS WITH EXTRAPOLATED INHALATION UNIT RISKS

Table B-1 contains chemicals on the Environmental Protection Agency's (EPA's) Integrated Risk Information System (IRIS) with Inhalation Unit Risk (IUR) values calculated by extrapolation using the default ventilation rate and body weight from the oral Cancer Slope Factor (CSF). These chemicals cause tumors remote from the respiratory tract. Also listed is the year EPA verified the cancer assessment. The list was compiled in September 2008.

EPA recommends that extrapolated IURs should be used with risk Equations 6 and 11 in the main document without additional modification for calculation of cancer risk by the inhalation route of exposure. It is generally not appropriate to make adjustments based on ventilation rate and body weight using the intake equation, because the amount of the chemical that reaches the target site of the chemical through the inhalation pathway is not a simple function of the inhalation rate and body weight. Risk assessors should outline the uncertainties involved in using extrapolated IURs in the risk characterization section of the risk assessment.

TABLE B-1 CHEMICALS WITH EXTRAPOLATED INHALATION UNIT RISKS ON IRIS	
Chemical	**Year of Verification**
Acrylamide[1]	1988
Aldrin	1987
Aramite	1991
Azobenzene	1988
Bromoform	1989
Chlordane	1997
Chloroform[1]	1987
DDT	1987
1,2-Dichloroethane	1986
Dieldrin	1987
1,2-Diphenylhydrazine	1986
Heptachlor	1987
Heptachlor epoxide	1987
Hexachlorobenzene	1989
Hexachlorobutadiene[1]	1986
Alpha-hexachlorocyclohexane	1986
Beta-hexachlorocyclohexane	1986
Technical-hexachlorocyclohexane	1986
Hexachlorodibenzo-p-dioxin mixture	1987
Hexachloroethane	1986
N-nitroso-di-n-butylamine	1986
N-nitrosodiethylamine	1986
N-nitrosodimethylamine	1986
N-nitrosopyrrolidine	1986
Polychlorinated biphenyls	1996
1,1,2,2-Tetrachloroethane	1986
1,1,1,2-Tetrachloroethane	1988
Toxaphene	1987
1,1,2-Trichloroethane	1986
2,4,6-Trichlorophenol	1989
[1] Note that this chemical's IUR is currently under review.

APPENDIX C

STSC's PROCESS FOR DERIVING ALTERNATIVE INHALATION TOXICITY VALUES

If Reference Concentration (RfC) and/or Inhalation Unit Risk (IUR) values for an inhaled contaminant are not available from the sources in the Environmental Protection Agency's (EPA's) Office of Solid Waste and Emergency Response (OSWER) hierarchy, risk assessors should first contact the National Center for Environmental Assessment's (NCEA's) Superfund Health Risk Technical Support Center (STSC) for guidance.[52] Risk assessors working on Superfund sites can contact STSC to determine whether a provisional peer-reviewed toxicity value (PPRTV) exists for a contaminant; if not, the risk assessor, in cooperation with the appropriate EPA Regional office may request that STSC develop a PPRTV document or that STSC develop an inhalation toxicity value as a "consult." The latter would be specific to the site in question only.

As a first choice, if human or whole animal studies exist providing a suitable No Observable Adverse Effect Level (NOAEL)/Lowest Observable Adverse Effect Level (LOAEL) or Point of Departure (POD) from a Benchmark Dose (BMD) analysis, this data normally will be used by STSC to develop an inhalation toxicity value. If, in addition, a suitable human inhalation physiologically based pharmacokinetic (PBPK) model exists that can be utilized to refine the dose metric to the target organ, then this information generally will be included in developing an inhalation toxicity value.

If no appropriate whole animal or human studies exist, but an appropriate peer reviewed human inhalation PBPK model exists that has been validated by experimental results, then STSC usually will attempt to derive an inhalation toxicity value from this model. If none exists, but a suitable PBPK animal inhalation models exists, STSC may attempt developing a human model and deriving an inhalation value.

PBPK modeling quantitatively describes the absorption/metabolism/distribution and elimination of the chemical from a point of entry (oral, inhalation, dermal) to the target organ(s). In some cases, an oral PBPK model can be extrapolated to the inhalation pathway, but care must be taken to consider direct pulmonary effects that may not be evident by oral dosing.

As a next approach, STSC typically will evaluate development of an inhalation toxicity value using a suitable surrogate chemical based on a quantitative structure-activity relationship (QSAR) model with structural selection criteria and solubility/toxicity considerations. STSC may evaluate possible surrogate chemicals based on several available structural models and provide a comparison. Selection of the appropriate surrogate may depend on the weight of evidence of these models.

---

[52] All contact with STSC should be performed by an EPA regional risk assessor. States and other entities should first contact their EPA regional risk assessor with questions on inhalation toxicity values. Regional risk assessors can then contact STSC on their behalf.

If STSC uses any of the methods for developing toxicity values other than from human or whole animal data, the value normally will be presented as a "screening" value with the caveat that it should not be used as a risk driver for a site without consultation with the STSC. The uncertainties associated with using toxicity values derived through PBPK modeling or QSAR, or with using a surrogate value should be described in the risk characterization portion of the risk assessment (see Section 9). Risk assessors are discouraged from performing simplistic route-to-route extrapolations from oral data using default assumptions about Inhalation Rate (IR) and body weight (BW).[53]

[53] If STSC indicates that no quantitative toxicity information for the inhalation route is available, the risk assessor should conduct a qualitative evaluation of this exposure route. The risk assessor should discuss in the uncertainty section of the risk assessment report the implications of not quantitatively assessing risks due to inhalation exposures to chemicals lacking inhalation toxicity data. See the section on Risk Characterization (Section 9) in the main text of this guidance for more information.

Conducting a Human Health Risk Assessment

On this page:

Planning | Hazard Identification | Dose-Response | Exposure Assessment | Risk Characterization

Planning and Scoping

Even a human health risk assessment starts with a good plan. Before anything though there is a need to make judgments early when planning major risk assessments regarding the purpose, scope, and technical approaches that will be used. To start, risk assessors will typically ask the following questions:

1. Who/What/Where is at risk?
    - Individual
    - General population
    - Lifestages such as children, teenagers, pregnant/nursing women
    - Population subgroups - highly susceptible (for example, due to asthma, genetics, etc.) and/or highly exposed (for example, based on geographic area, gender, racial or ethnic group, or economic status)

2. What is the environmental hazard of concern?

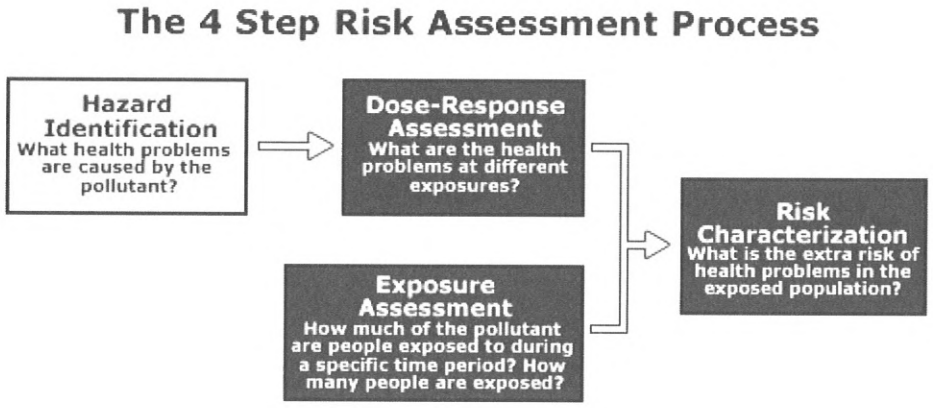
- Chemicals (single or multiple/cumulative risk)
- Radiation
- Physical (dust, heat)
- Microbiological or biological
- Nutritional (for example, diet, fitness, or metabolic state)
- Socio-Economic (for example, access to health care)

3. Where do these environmental hazards come from?

- Point sources (for example, smoke or water discharge from a factory; contamination from a Superfund site)
- Non-point sources (for example, automobile exhaust; agricultural runoff)
- Natural sources

4. How does exposure occur?

- Pathways (recognizing that one or more may be involved)
  - Air
  - Surface Water
  - Groundwater
  - Soil
  - Solid Waste
  - Food
  - Non-food consumer products, pharmaceuticals
- Routes (and related human activities that lead to exposure)
  - Ingestion (both food and water)
  - Contact with skin
  - Inhalation
  - Non-dietary ingestion (for example, "hand-to-mouth" behavior)



5. What does the body do with the environmental hazard and how is this impacted by factors such as age, race, sex, genetics, etc.?)
    - Absorption - does the body take up the environmental hazard
    - Distribution - does the environmental hazard travel throughout the body or does it stay in one place?
    - Metabolism - does the body break down the environmental hazard?
    - Excretion - how does the body get rid of it?

6. What are the health effects?
    - Example of some health effects include cancer, heart disease, liver disease and nerve disease.

7. How long does it take for an environmental hazard to cause a toxic effect? Does it matter when in a lifetime exposure occurs?
    - How long?
        - Acute - right away or within a few hours to a day
        - Subchronic - weeks or months (for humans generally less than 10% of their lifespan)
        - Chronic - a significant part of a lifetime or a lifetime (for humans at least seven years)
        - Intermittent
    - Timing
      Is there a critical time during a lifetime when a chemical is most toxic (e.g., fetal development, childhood, during aging)?

Step 1: Hazard Identification

The objective of Step 1 is to identify the types of adverse health effects that can be caused by exposure to some agent in question, and to characterize the quality and weight of evidence supporting this identification.

Step 1: Hazard identification is the first step of a human health risk assessment.

Hazard Identification is the process of determining whether exposure to a stressor can cause an increase in the incidence of specific adverse health effects (e.g., cancer, birth defects). It is also whether the adverse health effect is likely to occur in humans.

In the case of chemical stressors, the process examines the available scientific data for a given chemical (or group of chemicals) and develops a weight of evidence to characterize the link between the negative effects and the chemical agent.

Exposure to a stressor may generate many different adverse effects in a human: diseases, formation of tumors, reproductive defects, death, or other effects.

Sources of Data

Statistically controlled clinical studies on humans provide the best evidence linking a stressor, often a chemical, to a resulting effect. However, such studies are frequently not available since there are significant ethical concerns associated with human testing of environmental hazards.

Epidemiological studies involve a statistical evaluation of human populations to examine whether there is an association between exposure to a stressor and a human health effect. The advantage of these studies is that they involve humans while their weakness results from generally not having accurate exposure information and the difficulty of teasing out the effects of multiple stressors.

When data from human studies are unavailable, data from animal studies (rats, mice, rabbits, monkeys, dogs, etc) are relied on to draw inference about the potential hazard to humans. Animal studies can be designed, controlled, and conducted to address specific gaps in knowledge, but there are uncertainties associated with extrapolating results from animal subjects to humans.

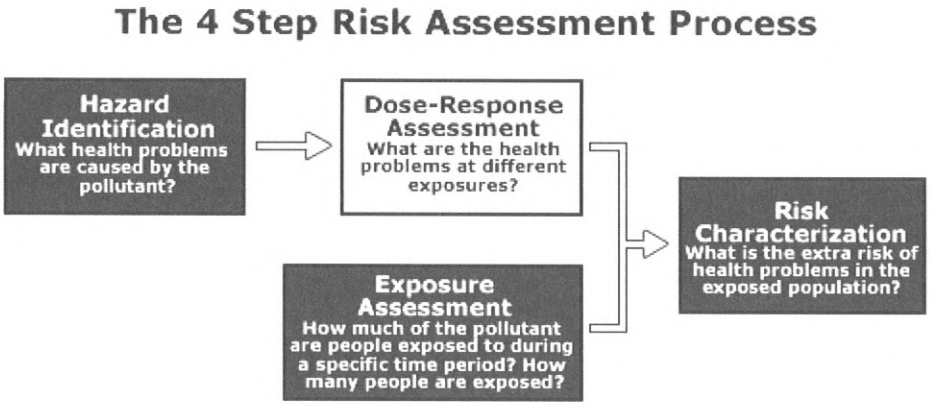
Key Components of Hazard Identification

A wide variety of studies and analysis are used to support a hazard identification analysis.

- Toxicokinetics considers how the body absorbs, distributes, metabolizes, and eliminates specific chemicals.

- Toxicodynamics focus on the effects that chemicals have on the human body. Models based on these studies can describe mechanisms by which a chemical may impact human health, thus providing insights into the possible effects of a chemical.

When assessing a chemical for potential carcinogenic behavior, current EPA practice is to focus on analysis of a mode of action. Mode of action is a sequence of key events and processes, starting with interaction of an agent and a cell, proceeding through operational and anatomical changes, and resulting in cancer formation. A given agent may work by more than one mode of action, both at different tumor sites as well as at the same site.



Analysis of mode of action is based on physical, chemical, and biological information that helps to explain key events in an agent's influence on tumor development.

A key component of hazard characterization involves evaluating the weight of evidence regarding a chemical's potential to cause adverse human health effects. The weight of evidence narrative may include some standard 'descriptors' that signify certain qualitative threshold levels of evidence or confidence have been met, such as 'Carcinogenic to humans' or 'Suggestive evidence of carcinogenic potential'.

Note: More specific information on hazard assessment approaches can be found in the specific risk assessment guidelines relevant for the kind of effect being considered.

Step 2: Dose Response

The objective of Step 2 is to document the relationship between dose and toxic effect.

Step 2: Dose-response assessment is the second step of a human health risk assessment.

A dose-response relationship describes how the likelihood and severity of adverse health effects (the responses) are related to the amount and condition of exposure to an agent (the dose provided). Although this webpage refers to the "dose-response" relationship, the same principles generally apply for studies where the exposure is to a concentration of the agent (e.g., airborne concentrations applied in inhalation exposure studies), and the resulting information is referred to as the "concentration-response" relationship.

The term "exposure-response" relationship may be used to describe either a dose-response or a concentration-response, or other specific exposure conditions.

Typically, as the dose increases, the measured response also increases. At low doses there may be no response. At some level of dose the responses begin to occur in a small fraction of the study population or at a low probability rate. Both the dose at which response begin to appear and the rate at which it increases given increasing dose can be variable between different pollutants, individuals, exposure routes, etc.

The shape of the dose-response relationship depends on the agent, the kind of response (tumor, incidence of disease, death, etc), and the experimental subject (human, animal) in question. For example, there may be one relationship for a response such as 'weight loss' and a different relationship for another response such as 'death'. Since it is impractical to study all possible relationships for all possible responses, toxicity research typically focuses on testing for a limited number of adverse effects.

> Typically, as the dose increases, the measured response also increases.

Upon considering all available studies, the response (adverse effect), or a measure of response that leads to an adverse effect (known as a 'precursor' to the effect), that occurs at the lowest dose is selected as the critical effect for risk assessment. The underlying assumption is that if the critical effect is prevented from occurring, then no other effects of concern will occur.

As with hazard identification, there is frequently a lack of dose-response data available for human subjects. When data are available, they often cover only a portion of the possible range of the dose-response relationship, in which case some extrapolation must be done in order to extrapolate to dose levels that are lower than the range of data obtained from scientific studies. Also, as with hazard identification, animal studies are frequently done to augment the available data.

Studies using animal subjects permit the use of study design to control the number and composition (age, gender, species) of test subjects, the levels of dose tested, and the measurement of specific responses. Use of a designed study typically leads to more meaningful statistical conclusions than does an uncontrolled observational study were additional confounding factors must also be considered for their impact on the conclusions.

However, dose-response relationships observed from animal studies are often at much higher doses that would be anticipated for humans, so must be extrapolated to lower doses, and animal studies must also be extrapolated from that animal species to

humans in order to predict the relationship for humans. These extrapolations, among others, introduce uncertainty into the dose-response analysis.

Basic Dose-Response Calculations & Concepts

As a component of the first step of the process discussed below, the scientific information is evaluated for a better biological understanding of how each type of toxicity or response (adverse effect) occurs; the understanding of how the toxicity is caused is called the "mode of action" (which is defined as a sequence of key events and processes, starting with interaction of an agent with a cell, proceeding through operational and anatomical changes, and resulting in the effect, for example, cancer formation).

Based on this mode of action, the Agency determines the nature of the extrapolation used in the second step of the process discussed above, either through non-linear or linear dose-response assessment.

A two-step process...

Step 1: Take an assessment of all data that are available or can be gathered through experiments. This is in order to document the dose-response relationship(s) over the range of observed doses (i.e, the doses that are reported in the data collected).

However, frequently this range of observation may not include sufficient data to identify a dose where the adverse effect is not observed (i.e., the dose that is low enough to prevent the effect) in the human population.

Step 2: This consists of extrapolation to estimate the risk (probably of adverse effect) beyond the lower range of available observed data. This is in order to make inferences about the critical region where the dose level begins to cause the adverse effect in the human population.

Non-linear dose-response assessment

Non-linear dose response assessment has its origins in the threshold hypothesis, which holds that a range of exposures from zero to some finite value can be tolerated by the organism with essentially no chance of expression of the toxic effect, and the threshold of toxicity is where the effects (or their precursors) begin to occur. It is often prudent to focus on the most sensitive members of the population; therefore, regulatory efforts are generally made to keep exposures below the population threshold, which is defined as the lowest of the thresholds of the individuals within a population.

If the "mode of action" information (discussed above) suggests that the toxicity has a threshold, which is defined as the dose below which no deleterious effect is expected to occur, then type of assessment is referred to by the Agency as a "non-linear" dose-response assessment. The term "nonlinear" is used here in a narrower sense than its usual meaning in the field of mathematics; a nonlinear assessment uses a dose-response relationship whose slope is zero (i.e., no response) at (and perhaps above) a dose of zero.

A No-Observed-Adverse-Effect Level (NOAEL) is the highest exposure level at which no statistically or biologically significant increases are seen in the frequency or severity of adverse effect between the exposed population and its appropriate control population. In an experiment with several NOAELs, the regulatory focus is normally on the highest one, leading to the common usage of the term NOAEL as the highest experimentally determined dose without a statistically or biologically significant adverse effect. In cases in which a NOAEL has not been demonstrated experimentally, the term "lowest-observed-adverse-effect level (LOAEL)" is used, which this is the lowest dose tested.

Mathematical modeling, which can incorporate more than one effect level (i.e., evaluates more data than a single NOAEL or LOAEL), is sometimes used to develop an alternative to a NOAEL known as a Benchmark Dose (BMD) or Benchmark Dose Lower-confidence Limit (BMDL). In developing the BMDL, a predetermined change in the response rate of an adverse effect (called the benchmark response or BMR; generally in the range of 1 to 10% depending on the power of a toxicity study) is selected, and the BMDL is a statistical lower confidence limit on the dose that produces the selected response. When the non-linear approach is applied, the LOAEL, NOAEL, or BMDL is used as the point of departure for extrapolation to lower doses.

The reference dose (RfD) is an oral or dermal dose derived from the NOAEL, LOAEL or BMDL by application of generally order-of-magnitude uncertainty factors (UFs). These uncertainty factors take into account the variability and uncertainty that are reflected in possible differences between test animals and humans (generally 10-fold or 10x) and variability within the human population (generally another 10x); the UFs are multiplied together: **10 x 10 = 100x.**

If a LOAEL is used, another uncertainty factor, generally 10x, is also used. In the absence of key toxicity data (duration or key effects), an extra uncertainty factor(s) may also be employed. Sometimes a partial UF is applied instead of the default value of 10x, and this value can be less than or greater than the default. Often the partial value is ½ log unit (the square root of 10) or 3.16 (rounded to 3-fold in risk assessment). Note, that when two UFs derived from ½ log units are multiplied together (3 x 3) the result is a 10 (equal to the full UF from which the two partial factors were derived).

Thus, the RfD is determined by use of the following equation: **RfD = NOAEL (or LOAEL or BMDL) / UFs**

In general, the RfD is defined as an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily oral exposure to the human population (including sensitive groups, such as asthmatics, or life stages, such as children or the elderly) that is likely to be without an appreciable risk of deleterious effects during a lifetime.

The **RfD is generally expressed** in **units of milligrams per kilogram of bodyweight per day: mg/kg/day**.

A similar term, know as reference concentration (RfC), is used to assess inhalation risks, where concentration refers to levels in the air (generally expressed in the units of milligrams agent per cubic meter of air: mg/m^3).

- For more information, please see A Review of the Reference Dose and Reference Concentration Processes <https://epa.gov/scientific-leadership/review-reference-dose-and-reference-concentration-processes>.

Linear dose-response assessment

If the "mode of action" information (discussed above) suggests that the toxicity does not have a threshold, then this type of assessment is referred to by the Agency as a "linear" dose-response assessment. In the case of carcinogens, if "mode of action" information is insufficient, then linear extrapolation is typically used as the default approach for dose-response assessment.

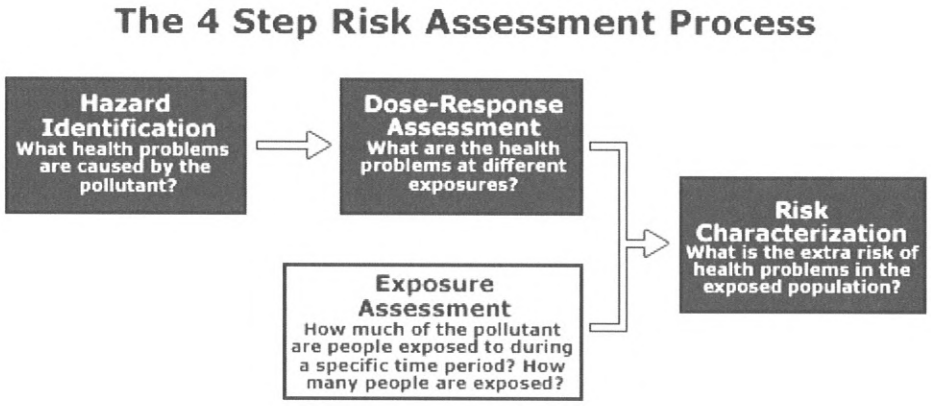
- For more detailed information, please see EPA's Guidelines for Carcinogen Risk Assessment <https://epa.gov/risk/guidelines-carcinogen-risk-assessment>.

In this type of assessment, there is theoretically no level of exposure for such a chemical that does not pose a small, but finite, probability of generating a carcinogenic response. The extrapolation phase of this type of assessment does not use UFs; rather, a straight line is drawn from the point of departure for the observed data (typically the BMDL) to the origin (where there is zero dose and zero response).

The slope of this straight line, called the slope factor or cancer slope factor, is use to estimate risk at exposure levels that fall along the line. When linear dose-response is used to assess cancer risk, EPA calculates excess lifetime cancer risk (i.e., probability that an individual will contract cancer over a lifetime) resulting from exposure to a contaminant by considering the degree to which individuals were exposed, as compared to the slope factor.

Thus, the cancer risk is determined by use of the following equation: **Cancer Risk = Exposure x Slope Factor**

Total cancer risk is calculated by adding the individual cancer risks for each pollutant in each pathway of concern (i.e., inhalation, ingestion, and dermal absorption), then summing the risk for all pathways.



A similar term, know as inhalation unit risk (IUR), is used to assess inhalation risks, where the exposure-response relationship refers to concentrations in the air.

Note: When there are alternative procedures having significant biological support, the Agency encourages assessments to be performed using these alternative procedures, if feasible, in order to shed light on the uncertainties in the assessment, recognizing that

the Agency may decide to give greater weight to one set of procedures than another in a specific assessment or management decision.

Step 3: Exposure Assessment

The objective of Step 3 is to calculate a numerical estimate of exposure or dose.

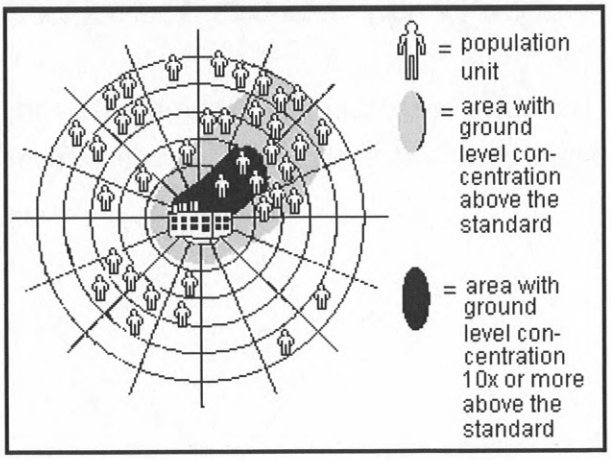
Step 3: Exposure Assessment is the third step of a human health risk assessment.

Exposure assessment is the process of measuring or estimating the magnitude, frequency, and duration of human exposure to an agent in the environment, or estimating future exposures for an agent that has not yet been released. An exposure assessment includes some discussion of the size, nature, and types of human populations exposed to the agent, as well as discussion of the uncertainties in the above information.

Exposure can be measured directly, but more commonly is estimated indirectly through consideration of measured concentrations in the environment, consideration of models of chemical transport and fate in the environment, and estimates of human intake over time.

Different Kinds of Doses. Exposure assessment considers both the exposure pathway (the course an agent takes from its source to the person(s) being contacted) as well as the exposure route (means of entry of the agent into the body). The exposure route is

generally further described as intake (taken in through a body opening, e.g. as eating, drinking, or inhaling) or uptake (absorption through tissues, e.g. through the skin or eye).



> EPA defines exposure as 'contact between an agent and the visible exterior of a person (e.g. skin and openings into the body)'.

The applied dose is the amount of agent at the absorption barrier that is available for absorption. The potential dose is the amount of agent that is ingested, inhaled, or applied to the skin. The applied dose may be less than the potential dose if the agent is only partly bioavailable.

The internal dose or absorbed dose is the amount of an agent that has been absorbed and is available for interaction with biologically significant receptors within the human body. Finally, the delivered dose is the amount of agent available for interaction with any specific organ or cell.

Range of Exposure. For any specific agent or site, there is a range of exposures actually experienced by individuals. Some individuals may have a high degree of contact for an extended period (e.g. factory workers exposed to an agent on the job). Other individuals may have a lower degree of contact for a shorter period (e.g. individuals using a recreational site downwind of the factory). EPA policy for exposure assessment requires consideration of a range of possible exposure levels.

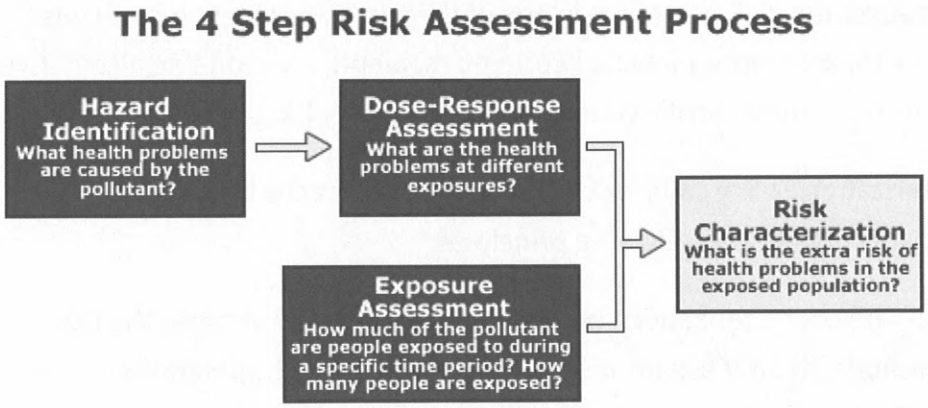
Two common scenarios for possible exposure are "Central Tendency" and "High End". "Central Tendency" exposure is an estimate of the average experienced by the affected population, based on the amount of agent present in the environment and the frequency and duration of exposure.

"High End" exposure is the highest dose estimated to be experienced by some individuals, commonly stated as approximately equal to the 90th percentile exposure category for individuals.

Figure: Showing the "range of exposure"

Quantifying Exposure. There are three basic approaches for quantifying exposure. Each approach is based on different data, and has different strengths and weaknesses; using the approaches in combination can greatly strengthen the credibility of an exposure risk assessment.

- **Point of Contact Measurement** - The exposure can be measured at the point of contact (the outer boundary of the body) while it is taking place, measuring both exposure concentration and time of contact, then integrating them;



- **Scenario Evaluation** - The exposure can be estimated by separately evaluating the exposure concentration and the time of contact, then combining this information;

- **Reconstruction** - the exposure can be estimated from dose, which in turn can be reconstructed through internal indicators (biomarkers, body burden, excretion levels, etc) after the exposure has taken place (reconstruction).

- For more information on exposure assessment methods, see the Guidelines for Exposure Assessment <https://epa.gov/risk/guidelines-exposure-assessment>.

Step 4: Risk Characterization

The objective of Step 4 is to summarize and integrate information from the proceeding steps of the risk assessment to synthesize an overall conclusion about risk.

Step 4: Risk characterization is the last step of a human health risk assessment.

A risk characterization conveys the risk assessor's judgment as to the nature and presence or absence of risks, along with information about how the risk was assessed, where assumptions and uncertainties still exist, and where policy choices will need to be made. Risk characterization takes place in both human health risk assessments and ecological risk assessments.

In practice, each component of the risk assessment (e.g. hazard assessment, dose-response assessment, exposure assessment) has an individual risk characterization written to carry forward the key findings, assumptions, limitations, and uncertainties. The set of these individual risk characterizations provide the information basis to write an integrative risk characterization analysis.

The final, overall risk characterization thus consists of the individual risk characterizations plus an integrative analysis.

The overall risk characterization informs the risk manager and others about the rationale behind EPA's approach to conducting the risk assessment.

Such as: Why EPA did what it did to assess the risk?

Principles of Conducting Risk Characterizations

A good risk characterization will restate the scope of the assessment, express results clearly, articulate major assumptions and uncertainties, identify reasonable alternative interpretations, and separate scientific conclusions from policy judgments.

EPA's Risk Characterization Policy calls for conducting risk characterizations in a manner that is consistent with the following principles:

- **Transparency** - The characterization should fully and explicitly disclose the risk assessment methods, default assumptions, logic, rationale, extrapolations, uncertainties, and overall strength of each step in the assessment.

- **Clarity** - The products from the risk assessment should be readily understood by readers inside and outside of the risk assessment process. Documents should be concise, free of jargon, and should use understandable tables, graphs, and equations as needed.

- **Consistency** - The risk assessment should be conducted and presented in a manner which is consistent with EPA policy, and consistent with other risk characterizations of similar scope prepared across programs within the EPA.

- **Reasonableness** - The risk assessment should be based on sound judgment, with methods and assumptions consistent with the current state-of-the-science and conveyed in a manner that is complete and balanced, informative.

These four principles are referred to collectively as TCCR. In order to achieve TCCR in a risk characterization, the same principles need to have been applied in all of the prior steps in the risk assessment which lead up to the risk characterization.

- For more information read the Risk Characterization Handbook <https://epa.gov/risk/risk-characterization-handbook>.

Risk Assessment for Carcinogenic Effects

EPA's first carcinogen risk assessment guidelines [1], published in 1986, were the product of nearly two decades of experience and scientific consensus building. EPA has since gained considerable experience in applying cancer risk assessment approaches. Concurrently, the science of risk assessment and toxicological testing has continued to evolve, and EPA has had to address situations not explicitly discussed in the 1986 guidelines, e.g., children's risk assessment. The update of EPA's carcinogen risk assessment guidelines in 2005 consolidated the Agency's experience, providing more comprehensive and transparent guidance on topics not fully developed in the original guidelines, and providing flexibility to accommodate anticipated advances in the science.

During the time between 1996 and 2005, EPA applied the principles and procedures of the draft revised guidelines on a case-by-case basis for new hazard identifications and dose-response assessments using interim draft guidelines that represented the

Dose–Response Assessment for Assessing Health Risks Associated With Exposure to Hazardous Air Pollutants

- Summary and Tables <https://epa.gov/fera/dose-response-assessment-assessing-health-risks-associated-exposure-hazardous-air-pollutants>

evolution of risk assessment methods rather than a dramatic shift in methodology. Since 2005, EPA has applied the new 2005 guidelines which reflect EPA's accumulated experience and advances in our knowledge on cancer assessment. On the other hand, assessments for many substances that were prepared under the 1986 guidelines continue to be valid. Therefore, the dose-response assessments of carcinogens reflect a mixture of the application of 1986 guidelines and the more recent guidelines.

Hazard Identification for Carcinogenic Effects. EPA's guidelines recognize three broad categories of data: (1) human data (primarily epidemiological); (2) results of long-term experimental animal bioassays; and (3) supporting data, including a variety of short-term tests for genotoxicity and other relevant properties, pharmacokinetic and metabolic studies, and structure-activity relationships. In hazard identification of carcinogens under the guidelines, human data, animal data, and supporting evidence are combined to characterize the weight-of-evidence (WOE) regarding the agent's potential as a human carcinogen. The current guidelines <https://epa.gov/risk/guidelines-carcinogen-risk-assessment>, finalized in 2005, recommend expressing WOE by narrative statements rather than only hierarchical categories, and expressing them separately for the oral and inhalation routes. The general categories recognized by the 2005 guidelines are [2]:

- Carcinogenic to Humans
- Likely to be Carcinogenic to Humans
- Suggestive Evidence of Carcinogenic Potential

- Sources of Chronic Dose-Response Information <https://epa.gov/fera/sources-chronic-dose-response-information>
- Prioritization of Data Sources for Chronic Exposure <https://epa.gov/fera/prioritization-data-sources-chronic-exposure>
- Additional Information, Adjustments and Special Cases for Dose-Response Values in Tables 1 and 2 <https://epa.gov/fera/additional-information-adjustments-and-special-cases-dose-response-values-tables-1-and-2>
- Sources of Acute Dose-Response Information <https://epa.gov/fera/sources-acute-dose-response-information>

- Inadequate Information to Assess Carcinogenic Potential
- Not Likely to be Carcinogenic to Humans

Under the 1986 guidelines, this WOE was summarized as fitting one of several hierarchic categories [1]:

Group A - Carcinogenic to Humans: Agents with adequate human data to demonstrate the causal association of the agent with human cancer (typically epidemiologic data).

Group B - Probably Carcinogenic to Humans: Agents with sufficient evidence (i.e., indicative of a causal relationship) from animal bioassay data, but either limited human evidence (i.e., indicative of a possible causal relationship, but not exclusive of alternative explanations; Group B1), or with little or no human data (Group B2).

Group C - Possibly Carcinogenic to Humans: Agents with limited animal evidence and little or no human data.

Group D - Not Classifiable as to Human Carcinogenicity: Agents without adequate data either to support or refute human carcinogenicity.

Group E - Evidence of Non-carcinogenicity for Humans: Agents that show no evidence for carcinogenicity in at least two adequate animal tests in different species or in both adequate epidemiologic and animal studies.

For each HAP that has been assessed for carcinogenicity under either set of guidelines, Table 1 of dose-response assessments compiled by the Office of Air Quality Planning and Standards <https://epa.gov/fera/dose-response-assessment-assessing-health-risks-associated-exposure-hazardous-air-pollutants> presents the category label specified by the most recent assessment (which may be via the current or past guidelines). At some point in the future, the table may also include excerpts of narrative WOEs. These WOE categories express the relative level of certainty that these agents may cause cancer in humans.

- The NRC Risk Assessment Paradigm <https://epa.gov/fera/nrc-risk-assessment-paradigm>
- **Risk Assessment for Carcinogens**
- Risk Assessment for Noncancer Effects <https://epa.gov/fera/risk-assessment-other-effects>

The categories specifically do not connote relative levels of hazard or degree of conservatism applied in developing a dose-response assessment. For example, a substance in group C (possible human carcinogen), under the 1986 guidelines, may impart a greater cancer risk to more people than another substance in group A (known human carcinogen), yet there is a greater certainty with regard to the risk associated with the latter. EPA's WOE classifications are focused on the amount and quality of evidence regarding whether or not a substance is carcinogenic to humans, not on the level of risk a substance might present. Dose-Response Assessment for Carcinogens. Since the publication of EPA's original cancer guidelines in 1986, considerable new knowledge has been developed regarding the processes of chemical carcinogenesis and the evaluation of human cancer risk. The 2005 guidelines [2] recognize both linear and nonlinear modes of action for carcinogens. When assessing the dose-response relationship under the guidelines, cancer data in the observable range are analyzed using a common dose-response model regardless of mode of action. The method of extrapolation to lower doses from the point of departure may vary depending on whether the available data indicate a linear or nonlinear mode of action.

Under the guidelines, linear extrapolation is appropriate when the evidence supports the mode of action of gene mutation due to direct DNA reactivity or another mode of action that is thought to be linear in the low dose region. A linear mode of action will also be the approach when available evidence is not sufficient to support a nonlinear extrapolation procedure, even in the absence of evidence of DNA reactivity. Nonlinear methods (including derivation of an oral reference dose or inhalation reference concentration) are to be used if there is sufficient evidence to support a nonlinear mode of action.

For linear carcinogens, EPA's current process of estimating cancer risk is based on the unit risk estimate (URE) for inhalation, and the carcinogenic potency slope (CPS) for ingestion. The URE represents the upper-bound excess lifetime cancer risk estimated to result from continuous exposure to an agent over a lifetime at a concentration of 1 $\mu g/m^3$ in air. The interpretation of the URE would be as follows: if the URE = 1.5 x 10-6 $\mu g/m^3$, no more than 1.5 excess tumors are expected to develop per 1,000,000 people if exposed all day, every day for a lifetime to a concentration of 1 µg of the chemical per cubic meter of air. The CPS is an upper bound, usually approximating a 95% confidence limit, on the increased cancer risk from a lifetime oral exposure to an agent. This estimate, usually expressed in units of proportion (of a population) affected per

mg/kg/day, is generally reserved for use in the low-dose region of the dose-response relationship, that is, for exposures corresponding to risks less than 1 in 100. The URE and CPS are plausible upper-bound estimates of the risk (i.e., the actual risk is likely to be lower, but may be greater). However, because the URE and CPS reflect unquantifiable assumptions about effects at low doses, their upper bounds are not true statistical confidence limits. The tabulated UREs and CPSs were developed by EPA and the California EPA, and were selected for use by a priority system <https://epa.gov/fera/prioritization-data-sources-chronic-exposure>.

Exposure Assessment Tools by Routes - Inhalation

On this page:

Overview | Methods | Calculations | Concentrations | Scenarios | Factors | Guidance | References

Overview

An exposure route is the way that a contaminant enters an individual or population after contact (IPCS, 2004). Typically, exposure occurs by one of three exposure routes—inhalation, ingestion, or dermal.

Inhalation exposure can result from breathing air that is contaminated with particulate matter (e.g., dust), vapors (e.g., volatile or semivolatile contaminants), or aerosols. Individuals can be exposed via the inhalation route during a variety of activities outdoors and indoors. Indoor receptors could also be exposed to outdoor air contaminants that infiltrate the indoor environment.

Estimating exposure from inhalation requires information on the concentrations of contaminants in the air and the timeframe over which inhalation exposure occurs. To calculate an inhaled dose, inhalation rates and receptor body weights might also be needed.

Calculations to estimate dose from inhalation are provided in this module as are various tools available for evaluating potential exposure concentrations. Exposure scenarios, exposure factors, and guidance for assessing exposure via inhalation are also provided.

Methods

When a contaminant is taken into the body via inhalation, the amount that gets into the body in a biologically available form is called the dose. There are a few different ways to measure dose (U.S. EPA, 1992):

- **Potential dose** is the amount of contaminant inhaled (i.e., amount that gets in the mouth or nose), not all of which is actually absorbed.

- **Applied dose** is the amount of contaminant at the absorption barrier (e.g., respiratory tract) that can be absorbed by the body.
- **Internal dose** is the amount of contaminant that gets past the exchange boundary (lung) and into the blood, or the amount of the contaminant that can interact with organs and tissues to cause biological effects.
- **Biologically effective dose** is the amount of contaminant that interacts with the internal target tissue or organ.

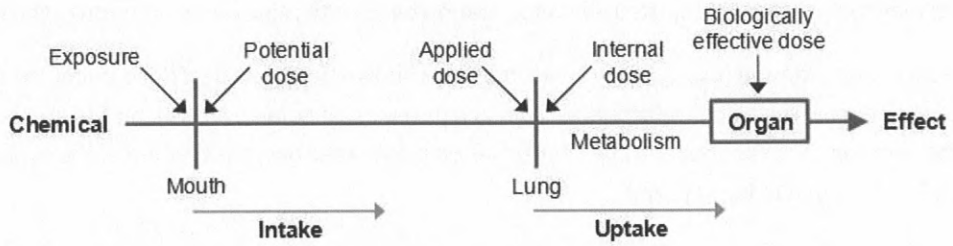

Illustration of Inhalation Route: Exposure and Dose (U.S. EPA, 1992)

The amount of chemical that is absorbed through the lung may vary from the amount of the substance that is inhaled. Thus, internal dose might differ from potential dose.

When using inhalation reference concentrations [RfCs] or inhalation unit risk [IURs] from the Integrated Risk Information System (IRIS) <https://epa.gov/iris> to characterize risk, it is not necessary to calculate the inhaled dose. This is because the IRIS methodology accounts for inhalation rates in the development of "dose-response" relationships. Instead, only an air concentration is needed to evaluate health concerns.

The methods used in developing noncancer inhalation dose-response values for IRIS are discussed in more detail in the U.S. EPA report entitled *Methods for Derivation of Inhalation Reference Concentrations and Application of Inhalation Dosimetry* <https://epa.gov/risk/methods-derivation-inhalation-reference-concentrations-and-application-inhalation-dosimetry> (U.S. EPA, 1994).

The Superfund Program has also recently updated its approach for determining inhalation risk. It has eliminated the use of inhalation rates when evaluating exposure to air contaminants. This is described in *Risk Assessment Guidance for Superfund (Part F, Supplemental Guidance for Inhalation Risk Assessment)* <https://epa.gov/risk/risk-assessment-guidance-superfund-rags-part-f> (U.S. EPA, 2009).

Inhalation - A Complicating Factor

The Agency defines exposure as the chemical concentration at the boundary of the body (U.S. EPA, 1992). In the case of inhalation, the situation is complicated by the fact that oxygen exchange with carbon dioxide takes place in the distal portion of the lung. The anatomy and physiology of the respiratory system as well as the characteristics of the inhaled agent diminishes the pollutant concentration in inspired air (potential dose) such that the amount of a pollutant that actually enters the body through the upper respiratory tract (especially

This updated methodology recommends that risk assessors use the concentration of the contaminant in air (C_{air}) as the exposure metric (e.g., mg/m^3) instead of the intake of a contaminant in air based on inhalation rate and body weight (dose; e.g., mg/kg-day).

the nasal-pharyngeal and tracheo-bronchial regions) and lung (internal dose) is less than that measured at the boundary of the body.

Calculations

Using EPA's current methodology, it is unnecessary to calculate an inhaled dose when using dose-response factors from IRIS in a risk assessment. However, inhalation risk assessments may require that an adjusted air concentration be used to represent continuous exposure.

The adjusted air concentration ($\mathbf{C_{air\text{-}adj}}$) may be estimated as shown below. As described under the Methods tab, for noncarcinogens, the air concentration is adjusted based on the time over which exposure occurs (i.e., the exposure duration). For carcinogens, the concentration is averaged over the lifetime of the exposed individual (often assumed to be 70 years).

$$\text{Cair-adj} = \text{Cair} \times \text{ET} \times \frac{1\text{day}}{24\text{ hours}} \times \text{EF} \times \frac{\text{ED}}{\text{AT}}$$

Where:
$\mathbf{C_{air}}$ = Concentration of contaminant in air (mg/m^3)
ET = Exposure time (hours/day)
EF = Exposure frequency (days/year)
ED = Exposure duration (years)
AT = Averaging time (days)

- The concentration in air ($\mathbf{C_{air}}$) is either a measured or modeled value. Air concentrations may be measured in the breathing zone of individuals using personal monitoring equipment or in indoor or outdoor air using stationary or portable monitoring devices. Air measurements may represent gas phase or particulate-phase contaminants, or both.
- **Temporal parameters** in the equation include the following:
  - Exposure time (**ET**) and exposure frequency (**EF**) refer to the frequency with which the exposure occurs and might be provided in hours per day and days per year, respectively.
  - Exposure duration (**ED**) is the amount of time that an individual or population is exposed to the contaminant being evaluated and is typically given in years.
  - Averaging time (**AT**) is the amount of time over which exposure is averaged and is equal to ED for assessing non-cancer risks. For chronic assessments (e.g., cancer), potential lifetime average daily dose (LADD) is calculated in which lifetime (LT, in days) is substituted for AT.

In some cases, it may be necessary to calculate an inhalation dose using the equation below. This algorithm can be used to calculate the average daily potential dose from inhalation of a contaminant in air.

The **potential dose** of a contaminant is the product of the contaminant concentration, inhalation rate, exposure time, exposure frequency, and exposure duration divided by the product of averaging time and body weight. The equation parameters below must be defined for each inhalation exposure scenario, and all parameters must be expressed in consistent units.

In some cases, unit conversion factors may be necessary. Average Daily Dose (ADD) is generally expressed as mass of contaminant per unit body weight over time (e.g., mg/kg-day).

$$\mathbf{ADD = Cair \times InhR \times ET \times EF \times ED/BW \times AT}$$

Where:
ADD = Average daily dose (mg/kg-day)
$\mathbf{C_{air}}$ = Concentration of contaminant in air (mg/m^3)
InhR = Inhalation rate (m^3/hour)
ET = Exposure time (hours/day)
EF = Exposure frequency (days/year)
ED = Exposure duration (years)
BW = Body weight (kg)
AT = Averaging time (days)

See above for descriptions for many of the relevant equation parameters. The additional parameters are described below.

- Inhalation rate (**InhR**) represents the volume of air inhaled over a specified timeframe. Long-term inhalation rates are typically expressed in units of m^3/day. Short-term inhalation rates are typically indexed to activity levels and are expressed in units of m^3/hour or m^3/minute. Assessors should choose inhalation rate data that best represent the population for which exposures are being assessed. Chapter 6 of the Handbook provides inhalation rate data for various age groups (see the Factors tab in this module).
- Body weight (**BW**) of an individual, typically expressed in kilograms (kg), is also included so that the dose is normalized to that value. Sometimes the inhalation rate is already normalized to body weight (e.g., in units of m^3/kg-day). In this case, a separate term for body weight would not be necessary.

Additional information on exposure scenarios involving the inhalation route can be found in the Indirect Estimation Module in the Approaches Tool Set.

Tool Type	Tools	Description

d	Agency for Toxic Substances and Disease Registry (ATSDR). ATSDR Comparison Value Viewer <https://www.atsdr.cdc.gov/sites/brownfields/cvviewer.html>	ATSDR's Comparison Value Viewer is a computer program that provides users with ATSDR health comparison values for chemicals in air, soil, and water.
m	Dutch National Institute for Health and Environment (RIVM). ConsExpo <https://www.rivm.nl/en/consexpo>	ConsExpo is a set of models that can be used to estimate and assess human exposure to substances from consumer products used indoors. This model is primarily used in the European Union's assessment of industrial chemicals (REACH).
m	The Lifeline Group. LifeLine™ User Manual v1.0 (Archived) <https://archive.epa.gov/scipoly/sap/meetings/web/pdf/lifeline.pdf>	LifeLine™ software for modeling aggregate and cumulative exposure to pesticides was designed to characterize population-based risks from pesticide residues in food and tap water as well as in the home following residential uses.
m	U.S. EPA. Air Pollutants Exposure Model (APEX) <https://www.epa.gov/fera/human-exposure-modeling-air-pollutants-exposure-model>	The APEX model can be used to estimate inhalation exposures that may occur at the local level or in specific microenvironments.
m	U.S. EPA. Chemical Screening Tool For Exposures and Environmental Releases (ChemSTEER) <https://www.epa.gov/tsca-screening-tools/chemsteer-chemical-screening-tool-exposures-and-environmental-releases>	ChemSTEER is used to estimate inhalation and dermal exposures to chemicals during chemical use and manufacture. Estimates also cover the releases of a chemical into the air, water, and land associated with occupational use.

	U.S. EPA. (2016). ExpoFIRST (Exposure Factors Interactive Resource for Scenarios Tool) <https://assessments.epa.gov/risk/document/&deid=322489>	ExpoFIRST is a standalone tool that draws from data in the EPA's Exposure Factors Handbook for quick, easy, and flexible development of human exposure scenarios. The tool develops these scenarios based on the selections made by the user in terms of the route of exposure of interest, the media of interest, exposure descriptor, receptor (age groups) and other demographics.
	U.S. EPA. Exposure and Fate Assessment Screening Tool (E-FAST) <https://www.epa.gov/tsca-screening-tools/e-fast-exposure-and-fate-assessment-screening-tool-version-2014>	Exposure and Fate Assessment Screening Tool (E-FAST) provides screening-level estimates of the concentrations of chemicals released to surface water and other media from consumer products.
	U.S. EPA. Industrial Source Complex Model (ISC3) <https://www.epa.gov/scram/air-quality-dispersion-modeling-alternative-models#isc3 >	ISC3 is a steady-state Gaussian plume model which can be used to assess pollutant concentrations from a wide variety of sources associated with an industrial complex.
	U.S. EPA. Industrial Waste Air Model (IWAIR) <https://www.epa.gov/smm/industrial-waste-air-model-iwair>	IWAIR is used to evaluate inhalation risks for workers and residents in the vicinity of waste management units. It includes models to estimate emissions, dispersion, and risk.

	U.S. EPA. (1997). Johnson and Ettinger Model for Subsurface Vapor Intrusion into Buildings <https://rais.ornl.gov/epa/je/guide.pdf>	This resource includes a series of models used to evaluate vapor intrusion into buildings. Several modifications have been made to the original models including the ability to edit data for existing chemicals, add new chemicals, and default values recommended in Appendix G of the EPA OSWER Draft Guidance for Evaluating the Vapor Intrusion to Indoor Air Pathway have been incorporated into the models. EPA has revised the models and added a series of new models.
	U.S. EPA. Multi-Chamber Concentration And Exposure Model (MCCEM) <https://www.epa.gov/tsca-screening-tools/forms/mccem-multi-chamber-concentration-and-exposure-model-download-and-install>	The MCCEM estimates average and peak indoor air concentrations of chemicals released from products or materials in residential buildings.
	U.S. EPA. Multimedia, Multipathway, and Multireceptor Exposure and Risk Assessment (3MRA) <https://www.epa.gov/ceam/3mra >	The Multimedia, Multipathway, Multireceptor Exposure and Risk Assessment (3MRA) is a screening-level tool that allows the assessment of potential human and ecological health risks resulting from long-term exposure to chemicals related to waste management.
	U.S. EPA. Swimmer Exposure Assessment Model (SWIMODEL) <https://www.epa.gov/pesticide-science-and-assessing-pesticide-risks/swimmer-exposure-assessment-model-swimodel>	SWIMODEL is a screening tool to conduct exposure assessments of pesticides found in indoor swimming pools and spas.
	U.S. EPA. Wall Paint Exposure Assessment Model (WPEM) <https://www.epa.gov/tsca-screening-tools/wall-paint-exposure-assessment-model-wpem>	WPEM is used to estimate the potential exposure of consumers and workers to the chemicals emitted from wall paint applied using a roller or a brush.

Concentrations

- Measuring Concentrations
- Modeling Concentrations
- Available Data

Sources of contamination to air, water, and soil and dust are discussed in the Media Tool Set. Media-specific concentrations are needed for estimating exposure via the inhalation route. Data and tools that can be used to estimate media-specific concentrations can also be found in the Media Tool Set.

Contamination of ambient (outdoor) air can occur from anthropogenic or natural sources. Examples of anthropogenic sources include: driving cars, trucks, or buses; burning coal, oil, and other fossil fuels; manufacturing chemicals or other products; degreasing, painting, or other industrial operations; and dry cleaning. Examples of natural sources include: gases emitted by the earth's crust [e.g., radon], and smoke and carbon dioxide [CO_2] released during forest fires.

Activities such as these may add gases and/or particles to the air. Some air pollutants can remain in the environment for long periods of time and can be transported in the atmosphere (e.g., by wind) hundreds of miles from their original source.

There are many sources of indoor air contaminants. These contaminants can enter buildings from the outside or may be generated from inside sources. Examples of indoor sources include: combustion of oil, gas, kerosene, coal, wood, and tobacco products; building materials and furnishings; and consumer products).

Reductions in building ventilation may increase indoor pollutant levels because indoor emissions are not being diluted by outdoor air or carried out of the indoor environment. Temperature and humidity can also contribute to increases in contaminant concentrations indoors.

Contaminant concentrations in air can be characterized based on measurements, modeling, and/or available monitoring data.

Measuring Concentrations

Information on sampling techniques and analytical methods is available to support the measurement of contaminants in potentially inhaled media.

Tool Type	Tools	Description
	American Society for Testing and Materials (ASTM). (2008). D6178: Standard Practice for Estimation of Short-term Inhalation Exposure to Volatile Organic Chemicals Emitted from Bedding Sets <https://www.astm.org/standards/d6178.htm>	This document describes procedures for estimating human inhalation exposure to volatile compounds emitted from bedding sets for the purpose of characterizing health risks due to short-term VOC exposures. Exposure estimates for specific raw materials and other components of different bedding sets could be evaluated and compared.

d	American Society for Testing and Materials (ASTM). Standards by Category <https://www.astm.org/products-services/standards-and-publications.html>	ASTM International (formerly known as the American Society for Testing and Materials, or ASTM) develops and provides support related to international voluntary consensus standards. Standards developed by ASTM include those relevant to occupational settings, including industrial hygiene and safety standards that specify methods for measuring the presence and amounts of chemical hazards used in the workplace. ASTM has also developed consumer product and related standards that cover methods for measuring chemicals related to a wide range of products.
d	National Institute for Occupational Safety and Health (NIOSH). (2016). NIOSH Pocket Guide to Chemical Hazards <https://www.cdc.gov/niosh/npg/>	The NIOSH Pocket Guide to Chemical Hazards informs workers, employers, and occupational health professionals about workplace chemicals and their hazards. The NPG gives general industrial hygiene information for hundreds of chemicals/classes. The NPG clearly presents key data for chemicals or substance groupings (such as cyanides, fluorides, manganese compounds) that are found in workplaces.
i	U.S. EPA. Air Modeling - Guidance for Air Toxics Modeling <https://www.epa.gov/scram/air-modeling-guidance-air-toxics-modeling>	This section provides miscellaneous guidance documents other than permit modeling or State Implementation Plan (SIP) attainment demonstrations.
i	U.S. EPA. Air Monitoring Methods <https://www.epa.gov/amtic/air-monitoring-methods>	This EPA site provides an approved method for conducting open-path remote sensing for ambient air concentrations with a Fourier transform infrared spectrometer.
i	U.S. EPA. Air Monitoring Methods – Criteria Pollutants <https://www.epa.gov/amtic/air-monitoring-methods-criteria-pollutants>	This EPA site lists designated reference or equivalent methods for monitoring and measuring ambient concentrations of criteria air pollutants—total suspended particulates (TSP), PM10, PM2.5, PM10–2.5, SO2, O3, CO, NO2, and Pb.

	U.S. EPA. Air Toxics – Monitoring Methods <https://www3.epa.gov/ttnamti1/airtox.html>	This EPA site provides descriptions and methodologies for monitoring and measuring hazardous air pollutants in ambient air.
	U.S. EPA. Compendium of Methods for the Determination of Inorganic Compounds in Ambient Air <https://www.epa.gov/amtic/compendium-methods-determination-inorganic-compounds-ambient-air>	This EPA site lists designated reference or equivalent methods for monitoring and measuring ambient concentrations of criteria air pollutants—total suspended particulates (TSP), PM10, PM2.5, PM10–2.5, SO2, O3, CO, NO2, and Pb.
	U.S. EPA. (2002). Guidance on Choosing a Sampling Design for Environmental Data Collection for Use in Developing a Quality Assurance Project Plan <https://www.epa.gov/quality/guidance-choosing-sampling-design-environmental-data-collection-use-developing-quality>	This guidance document provides information on how to develop sampling designs to collect environmental measurement data.
	U.S. EPA. (1992). Guidelines for Exposure Assessment: Table 2. Examples of Types of Measurements to Characterize Exposure-Related Media and Parameters <https://assessments.epa.gov/risk/document/&deid=15263>	This table illustrates some of the types of measurements used by exposure assessors, along with notes describing additional information often needed to use these measurements in estimating exposure or dose.
	U.S. EPA. (2004). Identification of Time-integrated Sampling and Measurement Techniques to Support Human Exposure Studies	This resource presents a literature review on the identification and evaluation of methods used to classify exposure.
	U.S. EPA. Superfund Analytical Services and Contract Laboratory Program (CLP) <https://www.epa.gov/clp>	This document is designed to offer the data reviewer guidance in determining the usability of analytical data generated through the U.S. EPA Contract Laboratory Program (CLP).

Modeling Concentrations

In the absence of measurement data, a variety of models can be used to estimate contaminant concentrations in air or dust that may be inhaled. Ambient air quality models may be used to estimate contaminant concentrations in air considering spatial-temporal characteristics (e.g., urban versus rural, geographic scale;

climate, season). Some models also account for population demographics and the time that the exposed populations spend in various microenvironments.

Indoor air models and models that evaluate air concentrations for specific exposure scenarios are also available. Examples include: inhalation of contaminants that volatilize from water while showering, and inhalation of contaminants that volatilize from pool water while swimming.

Tool Type	Tools	Description
	American Industrial Hygiene Association (AIHA). Industrial Hygiene Model (IH Mod) <https://www.aiha.org/get-involved/volunteergroups/pages/exposure-assessment-strategies-committee.aspx >	This website for the Exposure Assessment Strategies Committee provides links to tools for the practicing Industrial Hygienist including IH-Mod which is an Excel spreadsheet containing several algorithms used for calculating airborne concentrations of chemicals. Algorithms are provided for 12 models including well-mixed room, eddy diffusion, two-zone, field plume, and estimating contamination from small spills.
	California Air Resource Board (CARB). (2002). California Population Indoor Exposure Model (CPIEM) Version 2.0 User's Guide <https://www.arb.ca.gov/research/apr/past/98-327_usera.pdf>	This user's guide is comprehensive reference document for CPIEM, a Monte Carlo simulation model for estimating inhalation exposure for several indoor microenvironments (plus outdoors). CPIEM employs a mass-balance algorithm to estimate indoor pollutant concentration distributions using airborne concentrations and location/activity profiles.

	California Department of Toxic Substances Control (DTSC). CalTOX 1.5 Multimedia Risk Assessment Model <http://www.dtsc.ca.gov/assessingrisk/ctox_model.cfm>	The CalTOX Multimedia Risk Assessment model is a spreadsheet-based model for use in health-risk assessments that address contaminated soils and the contamination of adjacent air, surface water, sediments, and ground water. It includes a multimedia and transport transformation model, exposure scenario models, and addresses uncertainty in multimedia multi-pathway models.
	Dutch National Institute for Health and Environment (RIVM). ConsExpo <https://www.rivm.nl/en/consexpo>	ConsExpo is a set of models that can be used to estimate and assess human exposure to substances from consumer products used indoors. This model is primarily used in the European Union's assessment of industrial chemicals (REACH).
	ENVIRON. Comprehensive Air Quality Model with Extensions (CAMx) <http://www.camx.com/ >	The CAMx model allows for the assessment of gaseous and particulate air pollution (i.e., ozone, PM2.5, PM10, air toxics) over many scales ranging from sub-urban to continental. It also enables examination of source attribution.
	ICF International/Systems Applications International. (2006). Regional Modeling System for Aerosols and Deposition (REMSAD) <http://remsad.icfconsulting.com/>	REMSAD is used to provide a better understanding of the distributions, sources, and removal processes related to regional haze, particulate matter and other airborne pollutants, including soluble acidic components and toxics. Air concentrations and (wet and dry) deposition values are also available.

	The Lifeline Group. LifeLine™ User Manual v1.0 (Archived) <https://archive.epa.gov/scipoly/sap/meetings/web/pdf/lifeline.pdf>	LifeLine™ software for modeling aggregate and cumulative exposure to pesticides was designed to characterize population-based risks from pesticide residues in food and tap water as well as in the home following residential uses.
	U.S. EPA. AERMOD Modeling System <https://www.epa.gov/scram/air-quality-dispersion-modeling-preferred-and-recommended-models#aermod>	AERMOD can be used to model the movement of chemicals released from one or multiple sources through air; it incorporates air dispersion based on boundary layer turbulence structure and scaling concepts, including treatment of both surface and elevated sources, and both simple and complex terrain.
	U.S. EPA. Air: Fate, Exposure, and Risk Analysis (FERA) <https://www.epa.gov/fera>	This site describes multimedia fate and transport models (Total Risk Integrated Methodology [TRIM] - TRIM.FaTE); human exposure models (Air Pollutants Exposure Model [APEX/TRIM.Expo Inhalation], Hazardous Air Pollutant Exposure Model [HAPEM]); risk models (TRIM.Risk, Human Exposure Model [HEM]); as well as available documentation of methods for Fate, Exposure, and Risk Analysis as compiled by the Office of Air.
	U.S. EPA. Chemical Screening Tool For Exposures and Environmental Releases (ChemSTEER) <https://www.epa.gov/tsca-screening-tools/chemsteer-chemical-screening-tool-exposures-and-environmental-releases>	ChemSTEER is used to estimate inhalation and dermal exposures to chemicals during chemical use and manufacture. Estimates also cover the releases of a chemical into the air, water, and land associated with occupational use.

	U.S. EPA. Community Multiscale Air Quality Modeling System (CMAQ) <https://www.epa.gov/cmaq>	CMAQ is an air quality model and software suite designed to model multiple pollutants at multiple scales (from urban to regional). CMAQ can model tropospheric ozone, fine particles, toxics, acid deposition, and visibility degradation. It allows regulatory agencies to evaluate the impact of air quality management decisions and gives scientists the ability to probe, simulate, and understand chemical and physical interactions in the atmosphere.
	U.S. EPA. Estimation Program Interface (EPI) Suite <https://www.epa.gov/tsca-screening-tools/epi-suitetm-estimation-program-interface >	EPI Suite is a Microsoft Windows-based collection of physical/chemical property and environmental fate estimation programs developed by EPA's Office of Pollution Prevention Toxics (OPPT) and Syracuse Research Corporation (SRC).
	U.S. EPA. Exposure and Fate Assessment Screening Tool (E-FAST) <https://www.epa.gov/tsca-screening-tools/e-fast-exposure-and-fate-assessment-screening-tool-version-2014>	Exposure and Fate Assessment Screening Tool (E-FAST) provides screening-level estimates of the concentrations of chemicals released to surface water and other media from consumer products.
	U.S. EPA. Exposure Model for Soil-Organic Fate and Transport (EMSOFT) <https://assessments.epa.gov/risk/document/&deid=241704>	EMSOFT is used to explore how chemicals in the soil can vaporize and become an inhalation exposure risk in humans. The model can predict concentrations of soil contaminants, rates of transfer into the atmosphere, and potential ingestion and dermal contact risks. EMSOFT can also estimate average contaminant concentrations at a given soil depth over time.

	U.S. EPA. (2008). Guidance for the Sampling and Analysis of Lead in Indoor Residential Dust for Use in the Integrated Exposure Uptake Biokinetic (IEUBK) Model	This document recommends "methods for collecting and analyzing indoor residential dust data to estimate the mean concentration of lead in dust for use in the IEUBK model".
	U.S. EPA. Hazardous Air Pollutant Exposure Model (HAPEM) <https://www.epa.gov/fera/human-exposure-modeling-hazardous-air-pollutant-exposure-model-hapem>	HAPEM is a screening-level exposure model designed to assess average long-term inhalation exposures of the general population or a specific sub-population to various air toxics over spatial scales ranging from urban (large city) to national; activity patterns and multiple microenvironments can be considered.
	U.S. EPA. (2005). Human Health Risk Assessment Protocol (HHRAP) for Hazardous Waste Combustion Facilities	HHRAP describes the evaluation of multi-pathway, site-specific human health risk assessments and was developed specifically for assessment of hazardous waste combustors; it is applicable to other exposure scenarios as well.
	U.S. EPA. (2001). Indoor Air Quality Building Education and Assessment Model (I-BEAM), [CD-ROM]	I-BEAM is a guidance tool designed for use by building professionals and others interested in indoor air quality in commercial buildings. I-BEAM supplements EPA's Building Air Quality guidance and was designed to provide information about managing IAQ in commercial buildings. I-BEAM contains text, animation/visual, and interactive/calculation components that can be used to perform a number of diverse tasks.

	U.S. EPA. Integrated Exposure Uptake Biokinetic (IEUBK) Model for Lead in Children <https://www.epa.gov/superfund/lead-superfund-sites-software-and-users-manuals >	The IEUBK Model is designed to model exposure from lead in air, water, soil, dust, diet, and paint and other sources with pharmacokinetic modeling to predict blood lead levels in children 6 months to 7 years old. Links to the model and supporting documentation are provided at this website. (EPA's Adult Lead Model is used to predict blood lead levels in adults.)
	U.S. EPA. Internet Geographical Exposure Modeling System (IGEMS) <https://www.epa.gov/tsca-screening-tools/igemscsm-internet-geographical-exposure-modeling-systemchemical-safety-mapper>	IGEMS incorporates models and data for ambient air, surface water, soil, and ground water in one system. Each model produces results files that can be saved and used with statistical software applications or other database programs. IGEMS can create graphics and Geographical Information System (GIS) files for displaying environmental modeling results.
	U.S. EPA. Landfill Gas Emissions Model (LandGEM) <https://www.epa.gov/catc/clean-air-technology-center-products#software >	LandGem is an automated estimation tool with a Microsoft Excel interface to estimate emission rates for total landfill gas, methane, carbon dioxide, non-methane organic compounds, and individual air pollutants from municipal solid waste landfills.

	U.S. EPA. Lead at Superfund Sites: Software and Users' Manuals <https://www.epa.gov/superfund/lead-superfund-sites-software-and-users-manuals>	EPA's Integrated Exposure Uptake Biokinetic Model for Lead in Children is used to predict blood lead levels for children aged 6 months to 7 years. The ALM Model is designed to model exposure from lead in air, water, soil, dust, diet, and paint and other sources with pharmacokinetic modeling to predict blood lead levels adults. This page provides links for downloading these lead models and supporting documentation, including technical reports, guidance documents, FAQs, short sheets related to use of the IEUBK model and the ALM, and other links with additional information related to lead and lead cleanup.
	U.S. EPA. Models for Pesticide Risk Assessment: Atmospheric Models <https://www.epa.gov/pesticide-science-and-assessing-pesticide-risks/models-pesticide-risk-assessment#atmospheric >	EPA's Models for Pesticide Risk Assessment webpage provides links to aquatic, terrestrial, and atmospheric exposure models as well as health effects models used to assess the risk of a pesticide to human health or the environment. This website provides links to atmospheric models used to predict the deposition patterns of pesticides released into the atmosphere. Models include AGDISP (AGricultural DISPersal), AgDRIFT (modified version of AGDISP), PERFUM (Probabilistic Exposure and Risk Model for FUMigants), SOFEA (SOil Fumigant Exposure Assessment), and FEMS (Fumigant Exposure Modeling System).

	U.S. EPA. MOtor Vehicle Emission Simulator (MOVES) Model and Other Mobile Source Emissions Models <https://www.epa.gov/moves>	This website provides links to the MOtor Vehicle Emission Simulator (MOVES) and older models including the NONROAD model, National Mobile Inventory Model (NMIM), and MOBILE Model. MOVES is an emission modeling system that estimates emissions for mobile sources covering a broad range of pollutants. This tool allows users to perform multiple-scale analysis.
	U.S. EPA. Multimedia Models to Assess Exposures <https://www.epa.gov/ceam/multimedia-models-assess-exposures>	This site provides links to five multimedia models maintained by CEAM designed to quantify the movement and concentration of contaminants traveling through groundwater, surface water, and food chain media: Multimedia, Multi-pathway, Multi-receptor Exposure and Risk Assessment (3MRA) system; MINTEQA2 equilibrium speciation model; Multimedia Contaminant Fate, Transport, and Exposure Model (MMSOILS); Multimedia Exposure Assessment Model (MULTIMED); and Watershed Health Assessment Tools Investigating Fisheries (WHATIF) software.
	U.S. EPA. Risk Assessment and Modeling – Human Exposure Model (HEM) <https://www.epa.gov/fera/risk-assessment-and-modeling-human-exposure-model-hem>	HEM is used in performing risk assessments for major point sources of air toxics specifically for the inhalation exposure pathway. HEM provides ambient air concentrations for use with unit risk estimates and inhalation reference concentrations to estimate cancer risk and noncancer hazard, respectively, for the air toxics modeled.

	U.S. EPA. RISK, Indoor Air Quality Model	The RISK model allows calculation of individual exposure to indoor air pollutants from sources. RISK runs in the MS-Windows operating environment and allows users to calculate risk based on the calculated exposure.
	U.S. EPA. Simulation Tool Kit for Indoor Air Quality and Inhalation Exposure (IAQX), Version 1.0 User's Guide	This resource is a comprehensive guide to using IAQX version 1.
	U.S. EPA. Support Center for Regulatory Atmospheric Modeling (SCRAM) <https://www.epa.gov/scram>	This Web site is maintained by EPA's Air Quality Modeling Group (AQMG) and provides links to various air quality models, such as dispersion models, photochemical models, and receptor models. It also provides additional resources such as modeling applications and tools, and documentation and guidance for air quality models.

	U.S. EPA. Support Center for Regulatory Atmospheric Modeling – Air Quality Models <https://www.epa.gov/scram/air-quality-models>	EPA's Air Quality Modeling group maintains this site with documentation, guidance, and model code for dispersion, photochemical, and receptor models commonly used to support policy and regulatory decisions, including the assessment of control strategies and source impacts. Preferred/recommended dispersion models include the AERMOD Modeling System and the CALPUFF Modeling System. Links are provided to several photochemical models: Community Multi-scale Air Quality (CMAQ); Comprehensive Air quality Model with extensions (CAMx); Regional Modeling System for Aerosols and Deposition (REMSAD); and Urban Airshed Model Variable Grid (UAM-V®) as well as receptor models: Chemical Mass Balance (CMB); UNMIX; and Positive Matrix Factorization (PMF).
	U.S. EPA. TANKS Model <https://www3.epa.gov/ttn/chief/software/tanks/index.html>	TANKS is a Windows-based computer software program that estimates volatile organic compound (VOC) and hazardous air pollutant (HAP) emissions from fixed- and floating-roof storage tanks.
	U.S. EPA. Total Risk Integrated Methodology (TRIM) – TRIM.FaTE <https://www.epa.gov/fera/total-risk-integrated-methodology-trim-trimfate>	The TRIM.FaTE model estimates movement and transformation of pollutants over time. Outputs provide exposure estimates for environmental and human receptors that can be used in other models.

	U.S. EPA. (2007). User's Guide for the Integrated Exposure Uptake Model for Lead in Children (IEUBK)	This user's guide is a comprehensive reference for the IEUBK model, including installation, model inputs, analysis, and interpretation.
	U.S. EPA. (2000). Volatilization Rates from Water to Indoor Air Phase II <https://assessments.epa.gov/risk/document/&deid=20677>	EPA developed mass balance models for estimating chemical emissions for 5 tracer chemicals (acetone, ethyl acetate, toluene, ethylbenzene, and cyclohexane) from 4 sources (showers, dishwashers, washing machines, and bathtubs) to better characterize chemical volatilization from drinking water to indoor air. These experiments led to the development of source- and chemical-specific mass transfer coefficients, air exchange (ventilation) rates, and chemical stripping efficiencies. EPA also describes a set of protocols for estimating emission rates for chemicals other than the 5 tracer chemicals examined for this study.
	U.S. EPA. WATER9 Model <https://www3.epa.gov/ttn/chief/software/water/water9_3/index.html>	WATER9, a wastewater treatment model, estimates air emissions of individual waste constituents in wastewater collection, storage, treatment, and disposal facilities.
	U.S. EPA Region 3. Air Quality Analysis <https://www.epa.gov/air-quality-analysis >	This webpage includes information for air quality data analysts inside and outside EPA. The information provided supports EPA's NAAQS Review Process.

Available Data

Personal or stationary monitors can be used to measure air concentrations in the breathing zone of individuals who are closest to a source. Area monitors may be used to measure air concentrations that are representative of particular areas. In some cases, measurement data are used directly to estimate exposure concentrations. In other cases, measured data are used along with modeling to predict potential levels of exposure.

There are a number of information sources that provide monitoring data on contaminant concentrations in potentially inhaled media. Many of these data sources provide ambient air concentrations of contaminants at the national level and for other broad geographic areas such as cities, counties, and states. As such, they help EPA identify specific air toxics, and specific source sectors such as stationary sources or mobile sources, that generally produce the highest exposures and risks.

Tool Type	Tools	Description

di	Agency for Toxic Substances and Disease Registry (ATSDR). Toxicological Profiles for Hazardous Substances <https://www.atsdr.cdc.gov/toxprofiles/index.asp>	ATSDR has prepared approximately 300 toxicological profiles for hazardous substances found at National Priorities List (NPL) sites and other federal sites. Chemical names may be searched using the A to Z list on the ATSDR Toxic Substances Portal. Each Toxicological Profile contains a review of key studies and other data characterizing the exposure-related health effects and pertinent characteristics and processes that affect human exposures. Sections include other relevant information on releases to the environment, environmental fate, levels monitored in the environment, potential exposures, and analytical methods.
d	AIRNow. AIRNow website <https://airnow.gov/ >	AirNow provides air quality information in terms of the Air Quality Index (AQI) for five criteria air pollutants; data on trends as well as real-time indices are available from this collaboration between EPA and other federal, state and local agencies.

d	DeLima Associates. Consumer Product Information Database (CPID) <https://www.whatsinproducts.com/pages/index/1>	The CPID contains health effects information for nine categories of products used in the home and in some commercial/institutional settings that contain chemicals. The databases links brand names to health effects and provides label information, including brand name, ingredients and warnings, manufacturer information, health effect information, and properties and health studies for the chemical ingredients of brands.
d i	Health Canada. The Canadian House Dust Study <https://www.canada.ca/en/health-canada/services/environmental-workplace-health/environmental-contaminants/canadian-house-dust-study.html>	The Canadian House Dust Study sampled households between 2007 and 2010 to provide background levels of lead in Canadian homes. This web page provides links to several publications based on the results of the House Dust Study.
d	Jantunen, MJ; Hanninen, O; Katsouyanni, K; Knoppel, H; Kuenzli, N; Lebret, E; Maroni, M; Saarela, K; Sram, R; Zmirou, D. (1998). Air Pollution Exposure in European Cities: The EXPOLIS STUDY <https://www.thl.fi/expolis/files/final_report.pdf>	The EXPOLIS study measured personal exposure to PM2.5, 30 VOCs, CO, and NO2 in six European cities.

d	POET FP5 European project. (2006). POET Emission Inventory Documentation <http://accent.aero.jussieu.fr/documents/poet_documentation.pdf>	NASA estimated global emissions of gases (ozone precursors) from anthropogenic, natural, and biomass burning sources for the period 1990-2000. The emissions estimates are based on national activity data and emission factors.
d	U.S. Department of Health and Human Services (HHS). (2010). NLM® Household Products Database <https://www.nlm.nih.gov/pubs/techbull/ja10/ja10_sis_reprint_household_prods.html>	The Household Products Database (HPD) is based on the Consumer Product Information Database (CPID). The HPD contains information on products, manufacturers, chemical ingredients, safety and handling, and potential health effects for various product categories, including auto, inside the home, landscape/yard, home maintenance, pet care, arts/crafts, personal care products, home office, and pesticides. The National Library of Medicine® (NLM) HPD has been updated and now includes 10,000 brand name products, 3,214 ingredients, and 395 manufacturers. In addition, 4,111 products are now linked to the complete Material Safety Data Sheet (MSDS).

d	U.S. EPA. Air Data: Air Quality Data Collected at Outdoor Monitors Across the US <https://www.epa.gov/outdoor-air-quality-data>	The Air Data site provides access to yearly summaries of U.S. air pollution data collected at outdoor monitors across the US. This site has information about where air pollution comes from (emissions) and how much pollution is in the air outside our homes and work places (monitoring). Reports, visualization tools, and interactive maps are available on the site.
d i	U.S. EPA. (2018). Air Emissions Sources <https://www.epa.gov/air-emissions-inventories/national-emissions-inventory-nei>	This interactive National Emissions Inventory (NEI) Report explains how air emissions data are generated and used, and provides tools that explore emission trends and source contributions to air pollution. It highlights the most recent comprehensive and complete NEI, 2014 version 2, released in February 2018.
d	U.S. EPA. Air Quality System (AQS) <https://www.epa.gov/aqs >	AQS is EPA's database of ambient air monitoring data for criteria and hazardous air pollutants collected by states and tribes at more than 10,000 monitors across the country.

d	U.S. EPA. Air Toxics – National Air Toxics Trends Stations <https://www3.epa.gov/ttn/amtic/natts.html>	The NATTS Network was developed to monitor concentrations and trends in hazardous air pollutants (air toxics) at multiple sites across the U.S. The data can also be used to assess the effectiveness of emission reduction programs, assess and verify air quality models, and can serve as a direct input to source-receptor models.
d	U.S. EPA. Analysis and Products from NHEXAS; National Human Exposure Assessment Survey	This website provides links to NHEXAS work products.
d	U.S. EPA. Building Assessment Survey and Evaluation (BASE) Study <https://www.epa.gov/indoor-air-quality-iaq/building-assessment-survey-and-evaluation-study >	During the five year Building Assessment Survey and Evaluation (BASE) study, EPA collected measurements of indoor air quality in a nationally representative sample of public and commercial office buildings. Survey information about occupant perceptions of air quality is also available along with building specifications such as age and HV/AC characteristics. This site links to the raw data from this study as well as summary statistics and reports published using the data.

d	U.S. EPA. Chemical Data Reporting (CDR) <https://www.epa.gov/chemical-data-reporting>	CDR data are a collection of screening-level, exposure-related information on chemical substances. The CDR rule requires manufacturers and importers to submit information on the production and use of chemicals in commerce in large quantities. The CDR data constitute the most comprehensive source of basic screening-level, exposure-related information on chemicals available to EPA and include the following information when available: production volume, maximum concentration and physical form(s), total number of manufacturing, processing and use sites, total number of reasonably likely to be exposed manufacturing and industrial workers, and industrial processing and use and commercial and consumer use data.

d	U.S. EPA. Clean Air Status and Trends Network (CASTNET) Data <https://www.epa.gov/castnet>	CASTNET provides access to measured concentrations of criteria air pollutants from various rural monitoring sites around the United States; data can be used to assess trends in air quality, ecological effects, and atmospheric deposition.
d	U.S. EPA. Clearinghouse for Inventories and Emissions Factors (CHIEF) <https://www.epa.gov/chief>	This web site provides links to emissions inventories, air quality emission factors from the Emissions Factors and Policy Applications Center (EFPAC), Emissions Modeling Clearinghouse (EMCH), and monitoring techniques for air pollution control.

	U.S. EPA. CompTox Chemicals Dashboard <https://www.epa.gov/chemical-research/comptox-chemicals-dashboard>	The CompTox Chemicals Dashboard can be searched by chemical identifiers (e.g. DTXSID and CASRN), consumer product categories (i.e. view chemicals found in certain product types), and assays/genes associated with high-throughput screening data. Using high-throughput screening, living cells or proteins are exposed to chemicals and examined for subsequent changes that suggest potential biological responses. The Dashboard contains chemistry, toxicity and exposure information for over 900,000 chemicals, with over 300 chemical lists based on structure or category. Data and models within the Dashboard also help with efforts to identify chemicals of most need of further testing and reducing the use of animals in chemical testing.

d	U.S. EPA. Database of Sources of Environmental Releases of Dioxin-Like Compounds in the United States <https://assessments.epa.gov/risk/document/&deid=20797>	This resource is a repository of specific CDD/CDF emissions data from all known sources in the United States. The database information can be analyzed to track emissions of CDD/CDF over time, compare specific profiles between and among source categories, and develop source specific emission factors that can then be used to develop emission estimates.
d	U.S. EPA. Emission & Generation Resource Integrated Database (eGRID) < https://www.epa.gov/energy/emissions-generation-resource-integrated-database-egrid>	eGRID contains data on the environmental characteristics of almost all U.S.-based generated power. Characteristics recorded include air emissions for nitrogen oxides, sulfur dioxide, and other emissions as well as net generation, emission rates, and other attributes.

d	U.S. EPA. The Facility Registry Service (FRS) Query Page <https://www.epa.gov/enviro/frs-query-page>	The FRS Query Page allows users to retrieve selected facility data from the national systems listed. Search strategies include combinations of the facility name, geographic location, facility industrial classification, affiliated organization and contact, program category, and national systems.
i	U.S. EPA. (2011). Global Anthropogenic Non-CO2 Greenhouse Gas Emissions: 1990-2030 <https://www.epa.gov/sites/production/files/2016-08/documents/epa_global_nonco2_projections_dec2012.pdf>	This 2012 report provides estimated projections to 2030 for emissions from more than twenty emissions sources. The gases included in this report are methane, nitrous oxide, and fluorinated greenhouse gases (hydrofluorocarbons, perfluorocarbons, and sulfur hexafluoride).

d	U.S. EPA. (2008). Mobile Source Observation Database (MSOD) User Guide and Reference	The MSOD database contained emission test data from in-use mobile air pollution sources such as cars, trucks, and engines from trucks and nonroad vehicles. Data are available from 1982 to present and are intended to be representative of in-use vehicle emissions in the United States. A user and reference guide is available for this database.
d	U.S. EPA. National Air Quality: Status and Trends of Key Air Pollutants <https://www.epa.gov/air-trends>	This EPA website describes the trends in ambient air pollutants as well as emissions of those pollutants from different sources across the country.
d i	U.S. EPA. National Air Toxics Assessments (NATA) <https://www.epa.gov/national-air-toxics-assessment>	NATA is EPA's ongoing comprehensive evaluation of air toxics in the U.S. It is a screening tool for state/local/tribal agencies to prioritize pollutants, emission sources, and areas of interest for further study to gain a better understanding of risks.

d	U.S. EPA. National Emission Inventory (NEI) <https://www.epa.gov/air-emissions-inventories/national-emissions-inventory-nei>	EPA's NEI database contains information about sources that emit criteria air pollutants and their precursors, and hazardous air pollutants. The database includes estimates of annual air pollutant emissions from point, nonpoint, and mobile sources in the 50 States, the District of Columbia, Puerto Rico, and the Virgin Islands. EPA collects information about sources and releases an updated version of the NEI database every three years.
d	U.S. EPA. Ozone-Depleting Substances (ODS) <https://www.epa.gov/ozone-layer-protection/ozone-depleting-substances >	This site lists ozone-depleting substances (ODS) categorized by class, number scheme, and global warming potentials for ODS substitutes.
i	U.S. EPA. The Plain English Guide to the Clean Air Act <https://www.epa.gov/clean-air-act-overview/plain-english-guide-clean-air-act>	This site provides information on pollution prevention as it relates to consumer products use. Information on the contribution of consumer products to indoor and outdoor air pollution is provided.

d	U.S. EPA. RadNet <https://www.epa.gov/radnet>	RadNet, formerly Environmental Radiation Ambient Monitoring System (ERAMS), tracks radiation in the nation's air, precipitation, drinking water, and milk samples through a nationwide monitoring system.
d	U.S. EPA. Source Ranking Database <https://www.epa.gov/tsca-screening-tools/srd-source-ranking-database-users-guide-and-documentation-vol-1-and-vol-2>	The Source Ranking Database includes preliminary screening-level reviews of over 12,000 potential indoor pollution sources and allows for the identification of high-priority product and material categories for further evaluation.

d	U.S. EPA. SPECIATE Database <https://www.epa.gov/air-emissions-modeling/speciate-version-45-through-40>	SPECIATE is EPA's repository of total organic compound (TOC) and particulate matter (PM) speciation profiles of air pollution sources. The database can be used to create speciated emissions inventories for air quality modeling, estimate hazardous and toxic air pollutant emissions from total PM and TOC primary emissions, provide input to chemical mass balance receptor models, and verify profiles derived from ambient measurements using multivariate receptor models (e.g., factor analysis and positive matrix factorization).
d	U.S. EPA. (1987). Total Exposure Assessment Methodology (TEAM) Study <https://nepis.epa.gov/adobe/pdf/2000tty7.pdf>	EPA designed this study to develop methods to measure individual total exposure (through air, food, and water) to toxic and carcinogenic chemicals, including VOCs, pesticides, and carbon monoxide. Breath, personal air, outdoor air, and water samples were collected for 30 VOCs.

Scenarios

Inhalation exposure can be relevant for ambient air, indoor air, or both depending on the source and nature of the pollutant. Inhalation exposure can be estimated by first defining the exposure scenario of interest.

Exposure scenarios typically include information on the sources and pathways of exposure, contaminants of concern, and receptor populations. They might also describe a receptor population's activities that may affect exposure and the timeframe over which exposure occurs.

Inhalation exposure could occur over short durations (e.g., more than 24 hours, up to 30 days) or longer timeframes (e.g., more than 30 days), and can be associated with various types of activities (e.g., occupational, recreational, residential) in different indoor or outdoor environments.

The table below provides some examples of inhalation scenarios. The list of examples is not meant to be exhaustive; there are numerous other inhalation scenarios that may be constructed based on the specific needs of the assessment. There are also numerous variations of the examples provided in the table.

Examples of Inhalation Exposure Scenarios and Related Exposure Factors Handbook: 2011 Edition <https://epa.gov/expobox/about-exposure-factors-handbook> **Tables**

Medium	Receptor Population	Activity/Timeframe	Inhalation Rate	Exposure Period
Ambient air	General population; adults	Routine activity; long-term; adjusted air concentration	Not applicable	Chronic
Ambient air; contaminated site	School children	Playing during time spent in elementary school; dose calculation [Table 16-17]	Short-tem, activity-specific [Table 6-2]	Sub-chronic
Ambient air; source-related contaminant	Highly-exposed local population; adults and children	Routine; long-term-dose calculation	Daily [Table 6-1]	Chronic or sub-chronic, depending on lifestage
Outdoor air; particulates from contaminated site	Occupational; adults	Site-specific construction; short-term; adjusted air concentration	Not applicable	Acute
Indoor air	Infants or home-bound elderly adults	Routine; less than lifetime; adjusted air concentration	Not applicable	Sub-chronic

Medium	Receptor Population	Activity/Timeframe	Inhalation Rate	Exposure Period
Indoor air	Occupational	Working in contaminated office building; long-term occupational; adjusted air concentration [Table 16-8]	Not applicable	Chronic
Indoor air; consumer product use	Consumers	Cleaning with same consumer product over long timeframe [Chapter 17]	Short-term, activity-specific [Table 6-2]	Chronic
Indoor air; vapor intrusion from under-foundation source	Residential adults and children	Routine over lifetime; adjusted air concentration	Not applicable	Chronic
Indoor air; volatilization from water while showering	Residential adults and children	Showering daily [Table 16-1]	Short-term, activity-specific [Table 6-2]	Chronic or sub-chronic, depending on lifestage
Outdoor or indoor air; volatilization from swimming pool water	Recreators	Swimming over less than lifetime [Table 16-1]	Short-term, activity-specific [Table 6-2]	Sub-chronic
Indoor air; contamination in vehicle	Commuters; adults	Traveling in vehicle to and from work; less than lifetime [Table 16-24]	Short-term, activity-specific [Table 6-2]	Sub-chronic

Several resources are available that illustrate inhalation exposure scenarios.

Tool Type	Tools	Description

	U.S. EPA. (2014). Child-Specific Exposure Scenarios Examples	The Child-Specific Exposure Scenarios Examples provides common exposure pathways and tools for estimating exposure, dose, and adverse health effects in children. The scenarios provided in the document use data found in EPA's Child-Specific Exposure Factors Handbook and the Exposures Factors Handbook: 2011 Edition.
	U.S. EPA. (2004). Example Exposure Scenarios Assessment Tool <https://assessments.epa.gov/risk/document/&deid=85843>	This document presents a series of example exposure scenarios for various exposure pathways organized by route (i.e., ingestion, inhalation, or dermal) and demonstrates how data from the Exposure Factors Handbook can be applied for estimating exposures.
	U.S. EPA. (2016). ExpoFIRST (Exposure Factors Interactive Resource for Scenarios Tool) <https://assessments.epa.gov/risk/document/&deid=322489>	ExpoFIRST is a standalone tool that draws from data in the EPA's Exposure Factors Handbook for quick, easy, and flexible development of human exposure scenarios. The tool develops these scenarios based on the selections made by the user in terms of the route of exposure of interest, the media of interest, exposure descriptor, receptor (age groups) and other demographics.
	U.S. EPA. (2010). An Exposure Assessment of Polybrominated Diphenyl Ether <https://assessments.epa.gov/risk/document/&deid=210404>	EPA's exposure assessment of polybrominated diphenyl ether (PBDE) provides a comprehensive assessment of the exposure of Americans to PBDEs. The report includes information on the production, use, lifecycle, and environmental fate of these persistent organic chemicals, as well as measured environmental levels and human exposure.

	U.S. EPA. (2005). Human Health Risk Assessment Protocol (HHRAP) for Hazardous Waste Combustion Facilities	HHRAP describes the evaluation of multi-pathway, site-specific human health risk assessments and was developed specifically for assessment of hazardous waste combustors; it is applicable to other exposure scenarios as well.
	U.S. EPA. (1994). Methods for Derivation of Inhalation Reference Concentrations and Application of Inhalation Dosimetry <https://assessments.epa.gov/risk/document/&deid=71993>	This document describes EPA's methodology for estimation of inhalation reference concentrations (RfCs) as benchmark estimates of the quantitative dose-response assessment of chronic noncancer toxicity for individual inhaled chemicals. It also includes discussions of general principles of dose-response assessment for noncancer assessment process, criteria to select key studies for RfC derivation, and uncertainty and data gaps using this methodology.
	U.S. EPA. (1989). Risk Assessment Guidance for Superfund (RAGS): Volume I: Human Health Evaluation Manual (Part A) <https://www.epa.gov/risk/risk-assessment-guidance-superfund-rags-part>	The Risk Assessment Guidance for Superfund (RAGS): Volume I: Human Health Evaluation Manual (Part A) provides guidance for evaluating human health effects as part of a baseline risk assessment. This guidance document includes 10 chapters and two appendices describing topics including: planning, data collection and evaluation, exposure and toxicity assessment, and risk characterization.
	U.S. EPA. (2009). Risk Assessment Guidance for Superfund (RAGS): Volume I: Human Health Evaluation Manual (Part F, Supplemental Guidance for Inhalation Risk Assessment) <https://www.epa.gov/risk/risk-assessment-guidance-superfund-rags-part-f>	This document provides guidance for conducting inhalation risk assessments for Superfund sites.

	U.S. EPA. (2012). Standard Operating Procedures (SOPs) for Residential Pesticide Exposure Assessment <https://www.epa.gov/pesticide-science-and-assessing-pesticide-risks/standard-operating-procedures-residential-pesticide >	The 2012 Residential SOPs are based on the Guidelines for Exposure Assessment and present scenario-based assessments of exposure to pesticides in residential settings. New scenarios have been added to this edition for new products and uses; exposure algorithms for some existing exposure scenarios have been modified. Links to spreadsheets that can be used to perform the calculations are also available from this resource.
	U.S. EPA. (1996). Superfund Soil Screening Guidance <https://www.epa.gov/superfund/superfund-soil-screening-guidance>	The Soil Screening Guidance (SSG) is a framework proposed by U.S. EPA for developing risk-based, soil screening levels for protection of human health. The framework presents a tiered approach for site evaluation and screening-level development. The SSG is presented in three documents (fact sheet, user's guide, and technical background document) with an additional supplemental guidance. The supplemental guidance describes additional scenarios for soil screening evaluations for residential land use. It also updated the residential scenario presented in the original guidance, adding exposure pathways and incorporating new modeling data. The 2002 version includes updated dispersion modeling data for the residential air exposure model and new methods to develop SSLs for the migration of volatiles from subsurface sources into indoor air that supersede the 1996 guidance.

Factors

To estimate human exposure to contaminants in ambient or indoor air, information is needed about the exposed population(s), exposure pathways, and the concentrations of contaminants in air. When determining inhalation risk, inhalation rate and body weight

Microenvironments are the various changing spaces in which people spend their time that will influence how they will be exposed to contaminants. A

might not be needed. The Superfund Program's updated approach for determining inhalation risk eliminates use of inhalation rates when evaluating exposure to air contaminants (U.S. EPA, 2009).

However, if inhalation rates are needed, data are available in Chapter 6 of the Handbook. Inhalation rate is a volume of air inhaled per unit time. Long-term inhalation rates are reported as daily rates in units of m^3/day or m^3/kg-day. Short-term rates are described for various activities (e.g., walking, running, playing, housework, yard work) or activity levels (e.g., light, moderate, heavy) in units of m^3/minute.

Characteristics of the exposed individual and population are important to define because they determine inhalation rate. For example, inhalation rates will vary between children and adults due to differences in size, physiology, behavior, and activity levels. Individuals in an occupational setting are often assumed to be working harder than residents and so might be assumed to have a higher inhalation rate.

Personal characteristics also dictate activity patterns, which determine where a person is located (i.e., his/her microenvironments; see text box). They also pertain to the intensity of the activities in which the individual is engaged.

microenvironment can be defined as a space with a contaminant concentration that is assumed to be relatively well-mixed, homogeneous, and temporally constant while an individual is located within the microenvironment. Examples of microenvironments included in EPA assessments are automobiles, schools, work places, and other buildings. The *Exposure Factors Handbook: 2011 Edition* presents data on the amount of time that an individual is expected to spend in various microenvironments. For buildings, important factors might include size, volume, number of windows, and air exchange rates, and the Handbook provides information about these factors for both residential and nonresidential buildings (U.S. EPA, 2011).

The Exposure Factors Tab <https://epa.gov/expobox/exposure-assessment-tools-approaches-indirect-estimation-scenario-evaluation#factors> of the Indirect Estimation Module provides links to data on inhalation rates.

Activity-specific factors that may be relevant for assessing inhalation exposures associated with specific activity levels are available in Chapter 16 of the Handbook. Other exposure factors that might be needed for assessing inhalation exposures include:

Other exposure factors that might be needed for assessing inhalation exposures include:

- Body weight (**Chapter 8**)
- Consumer product use (**Chapter 17**)

- Life expectancy values, specifically when evaluating cancer risk (**Chapter 18**)
- Building characteristics when assessing indoor air exposures (**Chapter 19**)

Inhalation exposure factors should be selected to represent the age, gender (if appropriate), timeframe/activity level, and population group (e.g., resident, occupational worker) for the exposure scenario of interest.

> The Exposure Factors Tab <https://epa.gov/expobox/exposure-assessment-tools-approaches-indirect-estimation-scenario-evaluation#factors> of the Indirect Estimation Module provides links to data on other factors.

Guidance

The following sources provide helpful information for conducting exposure assessments involving the inhalation route of exposure.

- **Key:** Information sources
- Data sources
- Models

Tool Type	Tools	Description
	Australian Government Department of Health. (2012). Environmental Health Risk Assessment: Guidelines for Assessing Human Health Risks from Environmental Hazards <https://www.health.gov.au/sites/default/files/documents/2022/07/enhealth-guidance-guidelines-for-assessing-human-health-risks-from-environmental-hazards.pdf>	This guidance document provides information on basic concepts in environmental health risk assessment, including problem formulation, tiered approaches to exposure assessment. Specific guidance is provided for several topics related to exposure assessment including: assessing exposure from multiple routes and sources of exposure, probabilistic exposure modelling, and biomonitoring.

	California Air Resource Board (CARB). California Air Toxics Program <https://www.arb.ca.gov/toxics/toxics.htm>	The CARB Air Toxics Program institutes the process for identifying and controlling toxic air contaminants related to diesel activities, composite wood products, automobile coatings, residential waste burning, automotive maintenance and repair, dry cleaning, asbestos, ocean-going ship onboard incineration, and chrome plating and anodizing. The program also helps to increase public awareness regarding significant toxic exposures and methods for reducing risk.
	European Centre for Ecotoxicology and Toxicology of Chemicals (ECETOC). (2010). Guidance on Assessment Factors to Derive a Derived No-Effect Levels (DNEL) <http://www.ecetoc.org/wp-content/uploads/2014/08/ecetoc-tr-110-guidance-on-assessment-factors-to-derive-a-dnel.pdf>	This European guidance document provides a review of assessment factors (AF) used in Derived No-Effect Levels (DNEL), which are used by chemical manufacturers and importers to justify chemical safety assessments (CSA), as required by REACH. The review examined the validity of AF used in R.8 Guidance and predicts the increased difficulty of balancing DNEL with exposure predictions if the use of default AF continues.
	National Institute for Occupational Safety and Health (NIOSH). Respirator Selection Logic Guidance <https://www.cdc.gov/niosh/docs/2005-100/>	This document provides guidance to respirator program administrators on respirator selection in accordance with current respirator use and certification regulations and NIOSH policy.

	Occupational Safety and Health Administration (OSHA). Respiratory Protection eTool <https://www.osha.gov/sltc/etools/respiratory/respirator_selection.html>	This OSHA eTool provides guidance on selecting the appropriate respirator, developing a respirator change schedule, and complying with the OSHA respirator standard.
	Occupational Safety and Health Administration (OSHA). Technical Manual on Ventilation <https://www.osha.gov/otm/section-3-health-hazards/chapter-3>	This OSHA manual provides technical information and guidance on occupational safety and health issues and can be used by OSHA Compliance Safety and Health Officers to assist in hazard recognition and provide guidance in accident prevention.
	U.S. Consumer Product Safety Commission (CPSC). Carbon Monoxide <https://www.cpsc.gov/safety-education/safety-education-centers/carbon-monoxide-information-center>	This website provides links to various publications related to indoor air quality and consumer products.

m	U.S. Department of Energy (DOE). (1997). Office of Scientific and Technical Information (OSTI) Case Study Comparisons of Vapor Inhalation Risk Estimates <https://www.osti.gov/scitech/biblio/641268>	This paper describes two case studies that compare exposure concentrations and estimated human health risks from the RBCA vapor transport models and actual soil vapor concentration and soil vapor flux data. The first case study examines a residential property with petroleum hydrocarbon contamination; the second case study examines chlorinated hydrocarbon contamination in soil and groundwater at a Superfund site. The two approaches compared were the American Society for Testing and Materials (ASTM) Risk-Based Corrective Action (RBCA) model predictions versus site specific soil vapor data.
d	U.S. EPA. Acute Exposure Guideline Levels (AEGLs) Chemical Listing <https://www.epa.gov/aegl/access-acute-exposure-guideline-levels-aegls-values#chemicals >	AEGLs are airborne concentrations (expressed as ppm or mg/m3) that represent threshold exposure limits for the general public and are applicable to exposure periods up to 8 hours. There are three AEGL severity levels—AEGL-1, AEGL-2, and AEGL-3—with AEGL-3 being the most severe. From this website, AEGL information can be obtained using chemical name or cas. no. A compilation of AEGLs is also available for download.

i	U.S. EPA. Air Modeling Guidance and Support <https://www.epa.gov/scram/modeling-guidance-and-support>	The EPA's Air Quality Modeling Group (AQMG) provides leadership to the EPA Regions and State/local/tribal agencies on the selection and use of models in regulatory settings through national modeling guidance. This website provides links to models and guidance.
i	U.S. EPA. (2009). Asbestos: Protect Your Family <https://www.epa.gov/asbestos/protect-your-family>	This EPA website provides information on vermiculite consumer products that may contain asbestos.
i	U.S. EPA. Consumer Products: National Volatile Organic Compound Emission Standards <https://www.epa.gov/stationary-sources-air-pollution/consumer-products-national-volatile-organic-compound-emission>	EPA promulgated national volatile organic compound (VOC) emission standards for certain categories of consumer products pursuant to section 183(e) of the Clean Air Act (Act). Information on these standards can be found at this website.
d	U.S. EPA. Formaldehyde website <https://www.epa.gov/formaldehyde>	Building materials, smoking, household products, and the use of un-vented, fuel-burning appliances can be sources of formaldehyde in buildings. An important source of formaldehyde in homes may be pressed wood products made using adhesives that contain urea-formaldehyde (UF) resins. Information on formaldehyde sources may be found at this website.

i	U.S. EPA. (2007). Framework for Metals Risk Assessment <https://www.epa.gov/risk/framework-metals-risk-assessment>	The Framework for Metals Risk Assessment identifies the unique properties, issues, and processes that risk assessors need to consider when evaluating metal compounds in EPA risk assessments.
i	U.S. EPA. (1992). Guidelines for Exposure Assessment <https://assessments.epa.gov/risk/document/&deid=15263>	The Guidelines for Exposure Assessment is the "go to" resource for planning and conducting human exposure assessments. Guidance is also provided on general concepts of exposure, including definitions, uncertainty, suggestions for presenting results, and tools used for conducing exposure assessments. Information relevant to wildlife exposure to chemicals and human exposure to biological, radiological, and noise agents is also discussed in this resource.
d	U.S. EPA. Health Effects Assessment Summary Tables (HEAST) <https://assessments.epa.gov/risk/document/&deid=2877>	HEAST was developed by EPA for the Superfund and Resource Conservation and Recovery Act (RCRA) hazardous waste programs and includes human health risk and toxicity reference values for key contaminants at hazardous waste sites.

	U.S. EPA. (2005). Human Health Risk Assessment Protocol (HHRAP) for Hazardous Waste Combustion Facilities	HHRAP describes the evaluation of multi-pathway, site-specific human health risk assessments and was developed specifically for assessment of hazardous waste combustors; it is applicable to other exposure scenarios as well.
	U.S. EPA. Indoor Air Quality (IAQ) <https://www.epa.gov/indoor-air-quality-iaq>	This resource provides links to fact sheets, reports, and other sources of information related to indoor air quality.
	U.S. EPA. Indoor Air Quality (IAQ): Volatile Organic Compounds' (VOCs) Impact on Indoor Air Quality <https://www.epa.gov/indoor-air-quality-iaq/volatile-organic-compounds-impact-indoor-air-quality >	This website provides introductory-level information VOCs, including sources, health effects, levels in homes, steps to reduce exposure, and standards/guidelines.
	U.S. EPA. (2009). Metabolically-Derived Human Ventilation Rates: A Revised Approach Based upon Oxygen Consumption Rates <https://assessments.epa.gov/risk/document/&deid=202543>	This EPA report is a companion book to the EPA Exposure Factors Handbook. It provides a revised approach for calculating individual ventilation rates directly from oxygen consumption rate. This revised approach replaces previous approaches that relied on a ventilatory equivalent based on a person's fitness level.
	U.S. EPA. (1998). Methodology for Assessing Health Risks Associated with Multiple Pathways of Exposure to Combustor Emissions <https://assessments.epa.gov/risk/document/&deid=55525>	This guidance provides methodology on conducting indirect risk assessments for multiple pathways of exposure to combustor emissions.

	U.S. EPA. Mobile Source Pollution and Related Health Effects <https://www.epa.gov/mobile-source-pollution>	This website presents information on mobile source pollution, health effects, and strategies for reducing risk to the public from these pollutants.
	U.S. EPA. (1996). Occupational and Residential Exposure Test Guidelines for Indoor Inhalation Exposure <https://permanent.fdlp.gov/fbb/library/epa_875/875-1400.pdf>	This document is one of a series of test guidelines that have been developed by the Office of Prevention, Pesticides and Toxic Substances (OPPTS) for use in the testing of pesticides and toxic substances, and the development of test data that must be submitted to the Agency for review.
	U.S. EPA. (1996). Occupational and Residential Exposure Test Guidelines for Outdoor Inhalation Exposure <https://permanent.fdlp.gov/fbb/library/epa_875/875-1300.pdf>	This document is one of a series of test guidelines that have been developed by the Office of Prevention, Pesticides and Toxic Substances (OPPTS) for use in the testing of pesticides and toxic substances, and the development of test data that must be submitted to the Agency for review.

	U.S. EPA. (2015). OSWER Technical Guide for Assessing and Mitigating the Vapor Intrusion Pathway from Subsurface Vapor Sources to Indoor Air <https://www.epa.gov/sites/production/files/2015-09/documents/oswer-vapor-intrusion-technical-guide-final.pdf>	This OSWER guidance provides technical and policy recommendations for evaluation of subsurface vapor intrusion that may occur from subsurface soil and/or groundwater to building indoor air. It describes a recommended framework for assessing vapor intrusion to support risk management decisions. It also provides technical recommendations about monitoring and terminating building mitigation systems.
	U.S. EPA. (1989). Risk Assessment Guidance for Superfund (RAGS): Volume I: Human Health Evaluation Manual (Part A) <https://www.epa.gov/risk/risk-assessment-guidance-superfund-rags-part>	The Risk Assessment Guidance for Superfund (RAGS): Volume I: Human Health Evaluation Manual (Part A) provides guidance for evaluating human health effects as part of a baseline risk assessment. This guidance document includes 10 chapters and two appendices describing topics including: planning, data collection and evaluation, exposure and toxicity assessment, and risk characterization.
	U.S. EPA. (2009). Risk Assessment Guidance for Superfund (RAGS): Volume I: Human Health Evaluation Manual (Part F, Supplemental Guidance for Inhalation Risk Assessment) <https://www.epa.gov/risk/risk-assessment-guidance-superfund-rags-part-f>	This document provides guidance for conducting inhalation risk assessments for Superfund sites.

	U.S. EPA. (2012). Standard Operating Procedures (SOPs) for Residential Pesticide Exposure Assessment <https://www.epa.gov/pesticide-science-and-assessing-pesticide-risks/standard-operating-procedures-residential-pesticide >	The 2012 Residential SOPs are based on the Guidelines for Exposure Assessment and present scenario-based assessments of exposure to pesticides in residential settings. New scenarios have been added to this edition for new products and uses; exposure algorithms for some existing exposure scenarios have been modified. Links to spreadsheets that can be used to perform the calculations are also available from this resource.

	U.S. EPA. (1996). Superfund Soil Screening Guidance <https://www.epa.gov/superfund/superfund-soil-screening-guidance>	The Soil Screening Guidance (SSG) is a framework proposed by U.S. EPA for developing risk-based, soil screening levels for protection of human health. The framework presents a tiered approach for site evaluation and screening-level development. The SSG is presented in three documents (fact sheet, user's guide, and technical background document) with an additional supplemental guidance. The supplemental guidance describes additional scenarios for soil screening evaluations for residential land use. It also updated the residential scenario presented in the original guidance, adding exposure pathways and incorporating new modeling data. The 2002 version includes updated dispersion modeling data for the residential air exposure model and new methods to develop SSLs for the migration of volatiles from subsurface sources into indoor air that supersede the 1996 guidance.

Arsenic, inorganic; CASRN 7440-38-2

Human health assessment information on a chemical substance is included in the IRIS database only after a comprehensive review of toxicity data, as outlined in the IRIS assessment development process. Sections I (Health Hazard Assessments for Noncarcinogenic Effects) and II (Carcinogenicity Assessment for Lifetime Exposure) present the conclusions that were reached during the assessment development process. Supporting information and explanations of the methods used to derive the values given in IRIS are provided in the guidance documents located on the IRIS website.

STATUS OF DATA FOR Arsenic, inorganic

File First On-Line 02/10/1988

Category (section)	Assessment Available?	Last Revised
Oral RfD (I.A.)	yes	09/01/1991
Inhalation RfC (I.B.)	not evaluated	
Carcinogenicity Assessment (II.)	yes	06/01/1995

I. Chronic Health Hazard Assessments for Noncarcinogenic Effects

I.A. Reference Dose for Chronic Oral Exposure (RfD)

Substance Name — Arsenic, inorganic
CASRN — 7440-38-2
Last Revised — 09/01/1991

The oral Reference Dose (RfD) is based on the assumption that thresholds exist for certain toxic effects such as cellular necrosis. It is expressed in units of mg/kg-day. In general, the RfD is an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime. Please refer to the Background Document for an elaboration of these concepts. RfDs can also be derived for the noncarcinogenic health effects of substances that are also carcinogens. Therefore, it is essential to refer to other sources of information concerning the carcinogenicity of this

substance. If the U.S. EPA has evaluated this substance for potential human carcinogenicity, a summary of that evaluation will be contained in Section II of this file.

NOTE: There was not a clear consensus among Agency scientists on the oral RfD. Applying the Agency's RfD methodology, strong scientific arguments can be made for various values within a factor of 2 or 3 of the currently recommended RfD value, i.e., 0.1 to 0.8 ug/kg/day. It should be noted, however, that the RfD methodology, by definition, yields a number with inherent uncertainty spanning perhaps an order of magnitude. New data that possibly impact on the recommended RfD for arsenic will be evaluated by the Work Group as it becomes available. Risk managers should recognize the considerable flexibility afforded them in formulating regulatory decisions when uncertainty and lack of clear consensus are taken into account.

I.A.1. Oral RfD Summary

Critical Effect	Experimental Doses*	UF	MF	RfD
Hyperpigmentation, keratosis and possible vascular complications **Human Chronic oral exposure** **Tseng, 1977; Tseng et al., 1968**	NOAEL: 0.009 mg/L converted to 0.0008 mg/kg-day LOAEL: 0.17 mg/L converted to 0.014 mg/kg-day	3	1	3E-4 mg/kg-day

*Conversion Factors -- NOAEL was based on an arithmetic mean of 0.009 mg/L in a range of arsenic concentration of 0.001 to 0.017 mg/L. This NOAEL also included estimation of arsenic from food. Since experimental data were missing, arsenic concentrations in sweet potatoes and rice were estimated as 0.002 mg/day. Other assumptions included consumption of 4.5 L water/day and 55 kg bw (Abernathy et al., 1989). NOAEL = [(0.009 mg/L x 4.5 L/day) + 0.002 mg/day] / 55 kg = 0.0008 mg/kg-day. The LOAEL dose was estimated using the same assumptions as the NOAEL starting with an arithmetic mean water concentration from Tseng (1977) of 0.17 mg/L. LOAEL = [(0.17 mg/L x 4.5 L/day) + 0.002 mg/day] / 55 kg = 0.014 mg/kg-day.

I.A.2. Principal and Supporting Studies (Oral RfD)

Tseng, W.P. 1977. Effects and dose-response relationships of skin cancer and blackfoot disease with arsenic. Environ. Health Perspect. 19: 109-119.

Tseng, W.P., H.M. Chu, S.W. How, J.M. Fong, C.S. Lin and S. Yeh. 1968. Prevalence of skin cancer in an endemic area of chronic arsenicism in Taiwan. J. Natl. Cancer Inst. 40: 453-463.

The data reported in Tseng (1977) show an increased incidence of blackfoot disease that increases with age and dose. Blackfoot disease is a significant adverse effect. The prevalences (males and females combined) at the low dose are 4.6 per 1000 for the 20-39 year group, 10.5 per 1000 for the 40-59 year group, and 20.3 per 1000 for the >60 year group. Moreover, the prevalence of blackfoot disease in each age group increases with increasing dose. However, a recent report indicates that it may not be strictly due to arsenic exposure (Lu, 1990). The data in Tseng et al. (1968) also show increased incidences of hyperpigmentation and keratosis with age. The overall prevalences of hyperpigmentation and keratosis in the exposed groups are 184 and 71 per 1000, respectively. The text states that the incidence increases with dose, but data for the individual doses are not shown. These data show that the skin lesions are the more sensitive endpoint. The low dose in the Tseng (1977) study is considered a LOAEL.

The control group described in Tseng et al. (1968; Table 3) shows no evidence of skin lesions and presumably blackfoot disease, although this latter point is not explicitly stated. This group is considered a NOAEL.

The arithmetic mean of the arsenic concentration in the wells used by the individuals in the NOAEL group is 9 ug/L (range: 1-17 ug/L) (Abernathy et al., 1989). The arithmetic mean of the arsenic concentration in the wells used by the individuals in the LOAEL group is 170 ug/L (Tseng, 1977; Figure 4). Using estimates provided by Abernathy et al. (1989), the NOAEL and LOAEL doses for both food and water are as follows: LOAEL - [170 ug/L x 4.5 L/day + 2 ug/day (contribution of food)] x (1/55 kg) = 14 ug/kg/day; NOAEL - [9 ug/L x 4.5 L/day + 2 ug/day (contribution of food)] x (1/55 kg) = 0.8 ug/kg/day.

Although the control group contained 2552 individuals, only 957 (approximately 38%) were older than 20, and only 431 (approximately 17%) were older than 40. The incidence of skin lesions increases sharply in individuals above 20; the incidence of blackfoot disease increases sharply in individuals above 40 (Tseng, 1968; Figures 5, 6 and 7). This study is less powerful than it appears at first glance. However, it is certainly the most powerful study available on arsenic exposure to people.

This study shows an increase in skin lesions, 22% (64/296) at the high dose vs. 2.2% (7/318) at the low dose. The average arsenic concentration in the wells at the high dose is 410 ug/L and at the low dose is 5 ug/L (Cebrian et al., 1983; Figure 2 and Table 1) or 7 ug/L (cited in the abstract). The average water consumption is 3.5 L/day for males and 2.5 L/day for females. There were about an equal number of males and females in the study. For the dose estimates given below we therefore assume an average of 3 L/day. No data are given on the arsenic exposure from food or the body weight of the participants (we therefore assume 55 kg). The paper states that exposure times are directly related to chronological age in 75% of the cases. Approximately 35% of the participants in the study are more than 20 years old (Figure 1).

Exposure estimates (water only) are: high dose - 410 ug/L x 3 L/day x (1/55 kg) = 22 ug/kg/day; low dose - 5-7 ug/L x 3 L/day x (1/55 kg) = 0.3-0.4 ug/kg/day.

The high-dose group shows a clear increase in skin lesions and is therefore designated a LOAEL. There is some question whether the low dose is a NOAEL or a LOAEL since there is no way of knowing what the incidence of skin lesions would be in a group where the exposure to arsenic is zero. The 2.2% incidence of skin lesions in the low-dose group is higher than that reported in the Tseng et al. (1968) control group, but the dose is lower (0.4 vs. 0.8 ug/kg/day).

The Southwick et al. (1983) study shows a marginally increased incidence of a variety of skin lesions (palmar and plantar keratosis, diffuse palmar or plantar hyperkeratosis, diffuse pigmentation, and arterial insufficiency) in the individuals exposed to arsenic. The incidences are 2.9% (3/105) in the control group and 6.3% (9/144) in the exposed group. There is a slight, but not statistically significant increase in the percent of exposed individuals that have abnormal nerve conduction (8/67 vs. 13/83, or 12% vs. 16% (Southwick et al., 1983; Table 8). The investigators excluded all individuals older than 47 from the nerve conduction portion of the study. These are the individuals most likely to have the longest exposure to arsenic.

Although neither the increased incidence of skin lesions nor the increase in abnormal nerve conduction is statistically significant, these effects may be biologically significant because the same abnormalities occur at higher doses in other studies. The number of subjects in this study was insufficient to establish statistical significance.

Table 3 (Southwick et al., 1983) shows the annual arsenic exposure from drinking water. No data are given on arsenic exposure from food or the body weight (assume 70 kg). Exposure times are not clearly defined, but are > 5 years, and dose groups are ranges of exposure.

Exposure estimates (water only) are: dosed group - 152.4 mg/year x 1 year/365 days x (1/70) kg = 6 ug/kg/day; control group - 24.2 mg/year x year/365 days x (1/70) kg = 0.9 ug/kg/day.

Again because there are no data for a group not exposed to arsenic, there is some question if the control group is a NOAEL or a LOAEL. The incidence of skin lesions in this group is about the same as in the low-dose group from the Cebrian et al. (1983) study; the incidence of abnormal nerve conduction in the control group is higher than that from the low-dose group in the Hindmarsh et al. (1977) study described below. The control dose is comparable to the dose to the control group in the Tseng et al. (1968) and Hindmarsh et al. (1977) studies. The dosed group may or may not be a LOAEL, since it is does not report statistically significant effects when compared to the control.

This study shows an increased incidence of abnormal clinical findings and abnormal electromyographic findings with increasing dose of arsenic (Hindmarsh et al., 1977; Tables III and VI). However, the sample size is extremely small. Percentages of abnormal clinical signs possibly attributed to As were 10, 16, and 40% at the low, mid and high doses, respectively. Abnormal EMG were 0, 17 and 53% in the same three groups.

The exact doses are not given in the Hindmarsh et al. (1977) paper; however, some well data are reported in Table V. The arithmetic mean of the arsenic concentration in the high-dose and mid-dose wells is 680 and 70 ug/L, respectively. Figure 1 (Hindmarsh et al., 1977) shows that the average arsenic concentration of the low-dose wells is about 25 ug/L. No data are given on arsenic exposure from food. We assume daily water consumption of 2 liters and body weight of 70 kg. Exposure times are not clearly stated.

Exposure estimates (water only) are: low - 25 ug/L x 2 L/day x (1/70) kg = 0.7 ug/kg/day; mid - 70 ug/L x 2 L/day x (1/70) kg = 2 ug/kg/day; high - 680 ug/L x 2 L/day x (1/70) kg = 19 ug/kg/day.

The low dose is a no-effect level for abnormal EMG findings. However, because there is no information on the background incidence of abnormal clinical findings in a population with zero exposure to arsenic, there is no way of knowing if the low dose is a no-effect level or another marginal effect level for abnormal clinical findings. The low dose is comparable to the dose received by the control group in the Tseng (1977) and Southwick et al. (1983) studies.

The responses at the mid dose do not show a statistically significant increase but are part of a statistically significant trend and are biologically significant. This dose is an equivocal NOAEL/LOAEL. The high dose is a clear LOAEL for both responses.

As discussed previously there is no way of knowing whether the low doses in the Cebrian et al. (1983), Southwick et al. (1983) and Hindmarsh et al. (1977) studies are NOAELs for skin lesions and/or abnormal nerve conduction. However, because the next higher dose in the

Southwick and Hindmarsh studies only shows marginal effects at doses 3-7 times higher, the Agency feels comfortable in assigning the low doses in these studies as NOAELs.

The Tseng (1977) and Tseng et al. (1968) studies are therefore considered superior for the purposes of developing an RfD and show a NOAEL for a sensitive endpoint. Even discounting the people < 20 years of age, the control group consisted of 957 people that had a lengthy exposure to arsenic with no evidence of skin lesions.

The following is a summary of the defined doses in mg/kg-day from the principal and supporting studies:

1) Tseng (1977): NOAEL = 8E-4; LOAEL = 1.4E-2

2) Cebrian et al. (1983): NOAEL = 4E-4; LOAEL = 2.2E-2

3) Southwick et al. (1983): NOAEL = 9E-4; LOAEL = none (equivocal effects at 6E-3)

4) Hindmarsh et al., 1977: NOAEL = 7E-4; LOAEL = 1.9E-2 (equivocal effects at 2E-3)

I.A.3. Uncertainty and Modifying Factors (Oral RfD)

UF — The UF of 3 is to account for both the lack of data to preclude reproductive toxicity as a critical effect and to account for some uncertainty in whether the NOAEL of the critical study accounts for all sensitive individuals.

MF — None

I.A.4. Additional Studies/Comments (Oral RfD)

Ferm and Carpenter (1968) produced malformations in 15-day hamster fetuses via intravenous injections of sodium arsenate into pregnant dams on day 8 of gestation at dose levels of 15, 17.5, or 20 mg/kg bw. Exencephaly, encephaloceles, skeletal defects and genitourinary systems defects were produced. These and other terata were produced in mice and rats all at levels around 20 mg/kg bw. Minimal effects or no effects on fetal development have been observed in studies on chronic oral exposure of pregnant rats or mice to relatively low levels of arsenic via drinking water (Schroeder and Mitchner, 1971). Nadeenko et al. (1978) reported that intubation of rats with arsenic solution at a dose level of 25 ug/kg/day for a period of 7 months, including pregnancy, produced no significant embryotoxic effects and only infrequent slight expansion of ventricles of the cerebrum, renal pelvis and urinary bladder. Hood et al. (1977) reported that very high single oral doses of arsenate solutions (120 mg/kg) to pregnant

mice were necessary to cause prenatal fetal toxicity, while multiple doses of 60 mg/kg on 3 days had little effect.

Extensive human pharmacokinetic, metabolic, enzymic and long-term information is known about arsenic and its metabolism. Valentine et al. (1987) established that human blood arsenic levels did not increase until daily water ingestion of arsenic exceeded approximately 250 ug/day (approximately 120 ug of arsenic/L. Methylated species of arsenic are successively 1 order of magnitude less toxic and less teratogenic (Marcus and Rispin, 1988). Some evidence suggests that inorganic arsenic is an essential nutrient in goats, chicks, minipigs and rats (NRC, 1989). No comparable data are available for humans.

I.A.5. Confidence in the Oral RfD

Study — Medium
Database — Medium
RfD — Medium

Confidence in the chosen study is considered medium. An extremely large number of people were included in the assessment (> 40,000) but the doses were not well-characterized and other contaminants were present. The supporting human toxicity database is extensive but somewhat flawed. Problems exist with all of the epidemiological studies. For example, the Tseng studies do not look at potential exposure from food or other source. A similar criticism can be made of the Cebrian et al. (1983) study. The U.S. studies are too small in number to resolve several issues. However, the database does support the choice of NOAEL. It garners medium confidence. Medium confidence in the RfD follows.

I.A.6. EPA Documentation and Review of the Oral RfD

Source Document — This assessment is not presented in any existing U.S. EPA document.

This analysis has been reviewed by EPA's Risk Assessment Council on 11/15/1990. This assessment was discussed by the Risk Assessment Council of EPA on 11/15/1990 and verified through a series of meetings during the 1st, 2nd and 3rd quarters of FY91.

Other EPA Documentation — U.S. EPA, 1984, 1988

Agency Work Group Review — 03/24/1988, 05/25/1988, 03/21/1989, 09/19/1989, 08/22/1990, 09/20/1990

Verification Date — 11/15/1990

Screening-Level Literature Review Findings — A screening-level review conducted by an EPA contractor of the more recent toxicology literature pertinent to the RfD for Arsenic (inorganic) conducted in September 2002 identified one or more significant new studies. IRIS users may request the references for those studies from the IRIS Hotline at hotline.iris@epa.gov or (202)566-1676.

I.A.7. EPA Contacts (Oral RfD)

Please contact the IRIS Hotline for all questions concerning this assessment or IRIS, in general, at (202)566-1676 (phone), (202)566-1749 (FAX) or hotline.iris@epa.gov (internet address).

I.B. Reference Concentration for Chronic Inhalation Exposure (RfC)

Substance Name — Arsenic, inorganic
CASRN — 7440-38-2

Not available at this time.

II. Carcinogenicity Assessment for Lifetime Exposure

Substance Name — Arsenic, inorganic
CASRN — 7440-38-2
Last Revised — 06/01/1995

Section II provides information on three aspects of the carcinogenic assessment for the substance in question; the weight-of-evidence judgment of the likelihood that the substance is a human carcinogen, and quantitative estimates of risk from oral exposure and from inhalation exposure. The quantitative risk estimates are presented in three ways. The slope factor is the result of application of a low-dose extrapolation procedure and is presented as the risk per (mg/kg)/day. The unit risk is the quantitative estimate in terms of either risk per ug/L drinking water or risk per ug/cu.m air breathed. The third form in which risk is presented is a drinking water or air concentration providing cancer risks of 1 in 10,000, 1 in 100,000 or 1 in 1,000,000. The rationale and methods used to develop the carcinogenicity information in IRIS are described in The Risk Assessment Guidelines of 1986 (EPA/600/8-87/045) and in the IRIS Background Document. IRIS summaries developed since the publication of EPA's more recent Proposed Guidelines for Carcinogen Risk Assessment also utilize those Guidelines where

indicated (Federal Register 61(79):17960-18011, April 23, 1996). Users are referred to Section I of this IRIS file for information on long-term toxic effects other than carcinogenicity.

II.A. Evidence for Human Carcinogenicity

II.A.1. Weight-of-Evidence Characterization

Classification — A; human carcinogen

Basis — based on sufficient evidence from human data. An increased lung cancer mortality was observed in multiple human populations exposed primarily through inhalation. Also, increased mortality from multiple internal organ cancers (liver, kidney, lung, and bladder) and an increased incidence of skin cancer were observed in populations consuming drinking water high in inorganic arsenic.

II.A.2. Human Carcinogenicity Data

Sufficient. Studies of smelter worker populations (Tacoma, WA; Magma, UT; Anaconda, MT; Ronnskar, Sweden; Saganoseki-Machii, Japan) have all found an association between occupational arsenic exposure and lung cancer mortality (Enterline and Marsh, 1982; Lee-Feldstein, 1983; Axelson et al., 1978; Tokudome and Kuratsune, 1976; Rencher et al., 1977). Both proportionate mortality and cohort studies of pesticide manufacturing workers have shown an excess of lung cancer deaths among exposed persons (Ott et al., 1974; Mabuchi et al., 1979). One study of a population residing near a pesticide manufacturing plant revealed that these residents were also at an excess risk of lung cancer (Matanoski et al., 1981). Case reports of arsenical pesticide applicators have also corroborated an association between arsenic exposure and lung cancer (Roth, 1958).

A cross-sectional study of 40,000 Taiwanese exposed to arsenic in drinking water found significant excess skin cancer prevalence by comparison to 7500 residents of Taiwan and Matsu who consumed relatively arsenic-free water (Tseng et al., 1968; Tseng, 1977). Although this study demonstrated an association between arsenic exposure and development of skin cancer, it has several weaknesses and uncertainties, including poor nutritional status of the exposed populations, their genetic susceptibility, and their exposure to inorganic arsenic from non-water sources, that limit the study's usefulness in risk estimation. Dietary inorganic arsenic was not considered nor was the potential confounding by contaminants other than arsenic in drinking water. There may have been bias of examiners in the original study since no skin cancer or preneoplastic lesions were seen in 7500 controls; prevalence rates rather than mortality rates are the endpoint; and furthermore there is concern of the applicability of extrapolating data from Taiwanese to the U.S. population because of different background

rates of cancer, possibly genetically determined, and differences in diet other than arsenic (e.g., low protein and fat and high carbohydrate) (U.S. EPA, 1988).

A prevalence study of skin lesions was conducted in two towns in Mexico, one with 296 persons exposed to drinking water with 0.4 mg/L arsenic and a similar group with exposure at 0.005 mg/L. The more exposed group had an increased incidence of palmar keratosis, skin hyperpigmentation and hypopigmentation, and four skin cancers (histologically unconfirmed) (Cebrian et al. (1983). The association between skin cancer and arsenic is weak because of the small number of cases, small cohort size, and short duration follow-up; also there was no unexposed group in either town. No excess skin cancer incidence has been observed in U.S. residents consuming relatively high levels of arsenic in drinking water but the numbers of exposed persons were low (Morton et al., 1976; Southwick et al., 1981). Therapeutic use of Fowler's solution (potassium arsenite) has also been associated with development of skin cancer and hyperkeratosis (Sommers and McManus, 1953; Fierz, 1965); several case reports implicate exposure to Fowler's solution in skin cancer development (U.S. EPA, 1988).

Several follow-up studies of the Taiwanese population exposed to inorganic arsenic in drinking water showed an increase in fatal internal organ cancers as well as an increase in skin cancer. Chen et al. (1985) found that the standard mortality ratios (SMR) and cumulative mortality rates for cancers of the bladder, kidney, skin, lung and liver were significantly greater in the Blackfoot disease endemic area of Taiwan when compared with the age adjusted rates for the general population of Taiwan. Blackfoot disease (BFD, an endemic peripheral artery disease) and these cancers were all associated with high levels of arsenic in drinking water. In the endemic area, SMRs were greater in villages that used only artesian well water (high in arsenic) compared with villages that partially or completely used surface well water (low in arsenic). However, dose-response data were not developed (Chen et al. 1985).

A retrospective case-control study showed a significant association between duration of consuming high-arsenic well water and cancers of the liver, lung and bladder (Chen et al., 1986). In this study, cancer deaths in the Blackfoot disease endemic area between January 1980 and December 1982 were chosen for the case group. About 90% of the 86 lung cancers and 95 bladder cancers in the registry were histologically or cytologically confirmed and over 70% of the liver cancers were confirmed by biopsy or à-fetoprotein presence with a positive liver x-ray image. Only confirmed cancer cases were included in the study. A control group of 400 persons living in the same area was frequency-matched with cases by age and sex. Standardized questionnaires of the cases (by proxy) and controls determined the history of artesian well water use, socioeconomic variables, disease history, dietary habits, and lifestyle. For the cancer cases, the age-sex adjusted odds ratios were increased for bladder (3.90), lung (3.39), and liver (2.67) cancer for persons who had used artesian well water for 40 or more years when compared with controls who had never used artesian well water. Similarly, in a

15-year study of a cohort of 789 patients of Blackfoot disease, an increased mortality from cancers of the liver, lung, bladder and kidney was seen among BFD patients when compared with the general population in the endemic area or when compared with the general population of Taiwan. Multiple logistic regression analysis to adjust for other risk factors including cigarette smoking did not markedly affect the exposure-response relationships or odds ratios (Chen et al., 1988).

A significant dose-response relationship was found between arsenic levels in artesian well water in 42 villages in the southwestern Taiwan and age- adjusted mortality rates from cancers at all sites, cancers of the bladder, kidney, skin, lung, liver and prostate (Wu et al., 1989). An ecological study of cancer mortality rates and arsenic levels in drinking water in 314 townships in Taiwan also corroborated the association between arsenic levels and mortality from the internal cancers (Chen and Wang, 1990).

Chen et al. (1992) conducted a recent analysis of cancer mortality data from the arsenic-exposed population to compare risk of various internal cancers and compare risk between males and females. The study area and population have been described by Wu et al. (1989). It is limited to 42 southwestern coastal villages where residents have used water high in arsenic from deep artesian wells for more than 70 years. Arsenic levels in drinking water ranged from 0.010 to 1.752 ppm. The study population had 898,806 person-years of observation and 202 liver cancer, 304 lung cancer, 202 bladder cancer and 64 kidney cancer deaths. The study population was stratified into four groups according to median arsenic level in well water (< 0.10 ppm, 0.10- 0.29 ppm, 0.30-0.59 ppm and 60+ ppm), and also stratified into four age groups (< 30 years, 30-49 years, 50-69 years and 70+ years). Mortality rates were found to increase significantly with age for all cancers and significant dose- response relationships were observed between arsenic level and mortality from cancer of the liver, lung, bladder and kidney in most age groups of both males and females. The data generated by Chen et al. (1992) provide evidence for an association of the levels of arsenic in drinking water and duration of exposure with the rate of mortality from cancers of the liver, lung, bladder, and kidney. Dose-response relationships are clearly shown by the tabulated data (Tables II-V of Chen et al., 1992). Previous studies summarized in U.S. EPA (1988) showed a similar association in the same Taiwanese population with the prevalence of skin cancers (which are often non-fatal). Bates et al. (1992) and Smith et al. (1992) have recently reviewed and evaluated the evidence for arsenic ingestion and internal cancers.

II.A.3. Animal Carcinogenicity Data

Inadequate. There has not been consistent demonstration of carcinogenicity in test animals for various chemical forms of arsenic administered by different routes to several species (IARC, 1980). Furst (1983) has cited or reviewed animal carcinogenicity testing studies of nine

inorganic arsenic compounds in over nine strains of mice, five strains of rats, in dogs, rabbits, swine and chickens. Testing was by the oral, dermal, inhalation, and parenteral routes. All oxidation states of arsenic were tested. No study demonstrated that inorganic arsenic was carcinogenic in animals. Dimethylarsonic acid (DMA), the end metabolite predominant in humans and animals, has been tested for carcinogenicity in two strains of mice and was not found positive (Innes et al., 1969); however, this was a screening study and no data were provided. The meaning of non-positive data for carcinogenicity of inorganic arsenic is uncertain, the mechanism of action in causing human cancer is not known, and rodents may not be a good model for arsenic carcinogenicity testing. There are some data to indicate that arsenic may produce animal lung tumors if retention time in the lung can be increased (Pershagen et al., 1982, 1984).

II.A.4. Supporting Data for Carcinogenicity

A retrospective cohort mortality study was conducted on 478 British patients treated between 1945-1969 with Fowler's solution (potassium arsenite). The mean duration of treatment was 8.9 months and the average total oral consumption of arsenic was about 1890 mg (daily dose x duration). In 1980, 139 deaths had occurred. No excess deaths from internal cancers were seen after this 20-year follow-up. Three bladder cancer deaths were observed (1.19 expected, SMR 2.5) (Cuzick et al., 1982). A recent follow-up (Cuzick et al., 1992) indicated no increased mortality from all cancers but a significant excess from bladder cancer (5 cases observed/1.6 expected; SMR of 3.07). A subset of the original cohort (143 persons) had been examined by a dermatologist in 1970 for signs of arsenicism (palmar keratosis). In 1990, there were 80 deaths in the subcohort and 11 deaths from internal cancers. All 11 subjects had skin signs (keratosis-10, hyperpigmentation-5 and skin cancer-3). A case-control study of the prevalence of palmar keratoses in 69 bladder cancer patients, 66 lung cancer patients and 218 hospital controls (Cuzick et al., 1984), indicated an association between skin keratosis (as an indicator of arsenic exposure) and lung and bladder cancer. Above the age of 50, 87% of bladder cancer patients and 71% of lung cancer patients but only 36% of controls had one or more keratoses. Several case reports implicate internal cancers with arsenic ingestion or specifically with use of Fowler's solution but the associations are tentative (U.S. EPA, 1988).

Sodium arsenate has been shown to transform Syrian hamster embryo cells (Dipaolo and Casto, 1979) and to produce sister chromatid-exchange in DON cells, CHO cells, and human peripheral lymphocytes exposed in vitro (Wan et al., 1982; Ohno et al., 1982; Larramendy et al., 1981; Andersen, 1983; Crossen, 1983). Jacobson-Kram and Montalbano (1985) have reviewed the mutagenicity of inorganic arsenic and concluded that inorganic arsenic is inactive or very weak for induction of gene mutations in vitro but it is clastogenic with trivalent arsenic being an order of magnitude more potent than pentavalent arsenic.

Both the pentavalent and trivalent forms of inorganic arsenic are found in drinking water. In both animals and humans, arsenate (As+5) is reduced to arsenite (As+3) and the trivalent form is methylated to give the metabolites mononomethylarsinic acid (MMA) and dimethylarsonic acid (DMA) (Vahter and Marafante, 1988). The genotoxicity of arsenate (As+5) and arsenite (As+3) and the two methylated metabolites, MMA and DMA were compared in the thymidine kinase forward mutation assay in mouse lymphoma cells (Harrington-Brock et al. 1993; Moore et al., 1995, in press). Sodium arsenite (+3) and sodium arsenate (+5) were mutagenic at concentration of 1-2 ug/mL and 10-14 ug/mL, respectively, whereas MMA and DMA were significantly less potent, requiring 2.5-5 mg/mL and 10 mg/mL, respectively, to induce a genotoxic response. Based on small colony size the mutations induced were judged chromosomal rather than point mutations. The authors have previously shown that for chemicals having clastogenic activity (i.e., cause chromosomal mutations), the mutated cells grow more slowly than cells with single gene mutations and this results in small colony size. In the mouse lymphoma assay, chromosomal abberations were seen at approximately the same arsenic levels as TK forward mutations. Arsenate, arsenite and MMA were considered clastogenic but the abberation response with DMA was insufficient to consider it a clastogen. Since arsenic exerts its genotoxicity by causing chromosomal mutations, it has been suggested by the above authors that it may act in a latter stage of carcinogenesis as a progressor, rather than as a classical initiator or promotor (Moore et al., 1994). A finding which supports this process is that arsenate (8-16 uM) and arsenite (3 uM) have been shown to induce 2-10 fold amplification of the dihydrofolate reductase gene in culture in methotrexate resistant 3T6 mouse cells (Lee et al., 1988). Although the mechanism of induction in rodent cells is not known, gene amplification of oncogenes is observed in many human tumors. Inorganic arsenic has not been shown to mutate bacterial strains, it produces preferential killing of repair deficient strains (Rossman, 1981). Sodium arsenite (As+3) induces DNA-strand breaks which are associated with DNA-protein crosslinks in cultured human fibroblasts at 3 mM but not 10 mM (Dong and Luo, 1993) and it appears that arsenite inhibits the DNA repair process by inhibiting both excision and ligation (Jha et al., 1992; Lee-Chen et al., 1993).

The inhibitory effect of arsenite on strand-break rejoining during DNA repair was found to be reduced by adding glutathione to cell cultures (Huang et al., 1993). The cytotoxic effects of sodium arsenite in Chinese hamster ovary cells also has also found to correlate with the intracellular glutathione levels (Lee et al., 1989).

In vivo studies in rodents have shown that oral exposure of rats to arsenate (As+5) for 2-3 weeks resulted in major chromosomal abnormalities in bone marrow (Datta et al., 1986) and exposure of mice to As (+3) in drinking water for 4 weeks (250 mg As/L as arsenic trioxide) caused chromosomal aberrations in bone marrow cells but not spermatogonia (Poma et al., 1987); micronuclei in bone marrow cells were also induced by intraperitoneal dosing of mice with arsenate (DeKnudt et al., 1986; Tinwell et al., 1991). Chromosomal aberrations and sister

chromatid exchange have been seen in patients exposed to arsenic from treatment with Fowler's solution (Burgdorf et al., 1977) and subjects exposed occupationally (Beckman et al., 1977) but no increase in either endpoint was seen in lymphocytes of subjects exposed to arsenic in drinking water (Vig et al., 1984).

II.B. Quantitative Estimate of Carcinogenic Risk from Oral Exposure

II.B.1. Summary of Risk Estimates

Oral Slope Factor — 1.5E+0 per (mg/kg)/day

Drinking Water Unit Risk — 5E-5 per (ug/L)

Extrapolation Method — Time- and dose-related formulation of the multistage model (U.S. EPA, 1988)

Drinking Water Concentrations at Specified Risk Levels:

Risk Level	Concentration
E-4 (1 in 10,000)	2E+0 ug/L
E-5 (1 in 100,000)	2E-1 ug/L
E-6 (1 in 1,000,000)	2E-2 ug/L

II.B.2. Dose-Response Data (Carcinogenicity, Oral Exposure)

The Risk Assessment Forum has completed a reassessment of the carcinogenicity risk associated with ingestion of inorganic arsenic (U.S. EPA, 1988). The data provided in Tseng et al., 1968 and Tseng, 1977 on about 40,000 persons exposed to arsenic in drinking water and 7500 relatively unexposed controls were used to develop dose-response data. The number of persons at risk over three dose intervals and four exposure durations, for males and females separately, were estimated from the reported prevalence rates as percentages. It was assumed that the Taiwanese persons had a constant exposure from birth, and that males consumed 3.5 L drinking water/day and females consumed 2.0 L/day. Doses were converted to equivalent

doses for U.S. males and females based on differences in body weights and differences in water consumption and it was assumed that skin cancer risk in the U.S. population would be similar to the Taiwanese population. The multistage model with time was used to predict dose-specific and age-specific skin cancer prevalence rates associated with ingestion of inorganic arsenic; both linear and quadratic model fitting of the data were conducted. The maximum likelihood estimate (MLE) of skin cancer risk for a 70 kg person drinking 2 L of water per day ranged from 1E-3 to 2E-3 for an arsenic intake of 1 ug/kg/day. Expressed as a single value, the cancer unit risk for drinking water is 5E-5 per (ug/L). Details of the assessment are in U.S. EPA (1988).

Dose response data have not been developed for internal cancers for the Taiwanese population. The data of Chen et al. (1992) are considered inadequate at present.

II.B.3. Additional Comments (Carcinogenicity, Oral Exposure)

Eastern Research Group, under contract to EPA, convened an Expert Panel on Arsenic Carcinogenicity on May 21 and 22, 1997 (Eastern Research Group, 1997). The Expert Panel believed that, "it is clear from epidemiological studies that arsenic is a human carcinogen via the oral and inhalation routes (p. 20)." They also concluded, "that one important mode of action is unlikely to be operative for arsenic". The panel agreed that arsenic and its metabolites do not appear to directly interact with DNA (pp. 30-31)." In addition, the panel agreed that, "for each of the modes of action regarded as plausible, the dose-response would either show a threshold or would be nonlinear (p. 31)". The panel agreed, however, "that the dose-response for arsenic at low doses would likely be truly nonlinear, i.e., with a decreasing slope as the dose decreased. However, at very low doses such a curve might be linear but with a very shallow slope, probably indistinguishable from a threshold (p. 31)."

II.B.4. Discussion of Confidence (Carcinogenicity, Oral Exposure)

This assessment is based on prevalence of skin cancer rather than mortality because the types of skin cancer studied are not normally fatal. However, competing mortality from Blackfoot disease in the endemic area of Taiwan would cause the risk of skin cancer to be underestimated. Other sources of inorganic arsenic, in particular those in food sources have not been considered because of lack of reliable information. There is also uncertainty on the amount of water consumed/day by Taiwanese males (3.5 L or 4.5 L) and the temporal variability of arsenic concentrations in specific wells was not known. The concentrations of arsenic in the wells was measured in the early 1960s and varied between 0.01 and 1.82 ppm. For many villages 2 to 5 analyses were conducted on well water and for other villages only one analysis was performed; ranges of values were not provided. Since tap water was supplied to many areas after 1966, the arsenic-containing wells were only used in dry periods. Because

of the study design, particular wells used by those developing skin cancer could not be identified and arsenic intake could not be assigned except by village. Several uncertainties in exposure measurement reliability existed and subsequent analysis of drinking water found fluorescent substances in water that are possible confounders or caused synergistic effects. Uncertainties have been discussed in detail in U.S. EPA (1988). Uncertainties in exposure measurement can affect the outcome of dose- response estimation.

II.C. Quantitative Estimate of Carcinogenic Risk from Inhalation Exposure

II.C.1. Summary of Risk Estimates

Inhalation Unit Risk — 4.3E-3 per (ug/cu.m)

Extrapolation Method — absolute-risk linear model

Air Concentrations at Specified Risk Levels:

Risk Level	Concentration
E-4 (1 in 10,000)	2E-2 ug/cu.m
E-5 (1 in 100,000)	2E-3 ug/cu.m
E-6 (1 in 1,000,000)	2E-4 ug/cu.m

II.C.2. Dose-Response Data for Carcinogenicity, Inhalation Exposure

Tumor Type — lung cancer
Test animals — human, male
Route — inhalation, occupational exposure
Reference — Brown and Chu, 1983a,b,c; Lee-Feldstein, 1983; Higgins, 1982; Enterline and Marsh, 1982

Ambient Unit Risk Estimates (per µg/cu.m)

Ambient Unit Risk Estimates (per µg/cu.m)				
Exposure Source	**Study**	**Unit Risk**	**Geometric Mean Unit Risk**	**Final Estimated Geometric Mean Unit Risk**
Anaconda smelter	Brown and Chu Lee-Feldstein Higgins et al.	1.25E-3 2.80E-3 4.90E-3	2.56E-3	4.29E-3
ASARCO smelter	Enterline & Marsh	6.81E-3 7.60E-3	7.19E-3	4.29E-3

II.C.3. Additional Comments (Carcinogenicity, Inhalation Exposure)

A geometric mean was obtained for data sets obtained with distinct exposed populations (U.S. EPA, 1984). The final estimate is the geometric mean of those two values. It was assumed that the increase in age-specific mortality rate of lung cancer was a function only of cumulative exposures.

The unit risk should not be used if the air concentration exceeds 2 ug/cu.m, since above this concentration the unit risk may not be appropriate.

II.C.4. Discussion of Confidence (Carcinogenicity, Inhalation Exposure)

Overall a large study population was observed. Exposure assessments included air measurements for the Anaconda smelter and both air measurements and urinary arsenic for the ASARCO smelter. Observed lung cancer incidence was significantly increased over expected values. The range of the estimates derived from data from two different exposure areas was within a factor of 6.

II.D. EPA Documentation, Review, and Contacts (Carcinogenicity Assessment)

II.D.1. EPA Documentation

U.S. EPA. 1984, 1988, 1993

A draft of the 1984 Health Assessment Document for Inorganic Arsenic was independently reviewed in public session by the Environmental Health Committee of the U.S. EPA Science Advisory Board on September 22-23, 1983. A draft of the 1988 Special Report on Ingested Inorganic Arsenic; Skin Cancer; Nutritional Essentiality was externally peer reviewed at a two-day workshop of scientific experts on December 2-3, 1986. A draft of the Drinking Water Criteria Document for Arsenic was reviewed by the Drinking Water Committee of the U.S. EPA Science Advisory Board on March 10, 1993. The comments from these reviews were evaluated and considered in the revision and finalization of these reports.

II.D.2. EPA Review (Carcinogenicity Assessment)

Agency Work Group Review — 01/13/1988, 12/07/1989, 02/03/1994

Verification Date — 02/03/1994

Screening-Level Literature Review Findings — A screening-level review conducted by an EPA contractor of the more recent toxicology literature pertinent to the cancer assessment for Arsenic (inorganic) conducted in September 2002 identified one or more significant new studies. IRIS users may request the references for those studies from the IRIS Hotline at hotline.iris@epa.gov or (202)566-1676.

II.D.3. EPA Contacts (Carcinogenicity Assessment)

Please contact the IRIS Hotline for all questions concerning this assessment or IRIS, in general, at (202)566-1676 (phone), (202)566-1749 (FAX) or hotline.iris@epa.gov (internet address).

VII. Revision History

Substance Name — Arsenic, inorganic
CASRN — 7440-38-2

Date	Section	Description
06/30/1988	II.C.1.	Inhalation slope factor changed
09/01/1991	I.A.	Oral RfD summary now on-line
06/01/1995	II.	Carcinogenicity assessment replaced

Date	Section	Description
12/03/2002	I.A.6., II.D.2.	Screening-Level Literature Review Findings message has been added.

VIII. Synonyms

Substance Name — Arsenic, inorganic
CASRN — 7440-38-2
Last Revised — 02/10/1988

- 7440-38-2
- Arsenic
- Arsenic, inorganic
- gray-arsenic

Symbol	Definition (units)	Default	Reference
	Miscellaneous Variables		
TR	target risk	1×10^{-6}	Selected by user
THQ	target hazard quotient	0.1	Selected by user
RBA	relative bioavailability factor	Arsenic = 0.6 All Others = 1	U.S. EPA 2012
K	Andelman Volatilization Factor (L/m^3)	0.5	U.S. EPA 1991b (pg. 20)
K_p	Dermal Permeability Constant (cm/hour)	Contaminant-specific Inorganic default = 0.001	U.S. EPA 2004 Exhibit 3-1 and Section 3.1.2.1
$K_{p,ve}$	Steady-state Permeability Coefficient (cm/hour)	Contaminant-specific $K_{p,ve} = K_{ew} D_e / L_e$, K_{ew} = 1 assuming the viable epidermis (ve) (cm/hr) behaves essentially as water; $L_e = 10^{-2}$ cm, $De = 7.1 \times 10^{-6}$/MW cm^2/s assuming $D_e = 10^{-6}$ cm^2/s when MW = 50 (Bunge and Cleek, 1995)	U.S. EPA 2004
K_{ew}	Equilibrium Partition Coefficient between epidermis and water for the absorbing chemical (unitless)	Contaminant-specific	U.S. EPA 2004
D_{sc}	Effective diffusion coefficient for chemical transfer through the stratum corneum (cm2/hr)	Contaminant-specific	U.S. EPA 2004
B	Dimensionless ratio of the permeability coefficient of a compound through the stratum corneum relative to its permeability coefficient across the viable epidermis (ve) (unitless)	Contaminant-specific	U.S. EPA 2004
t^*	Time to reach steady-state (hr)	Contaminant-specific	U.S. EPA 2004
τ_{event}	Lag time per event (hr/event)	Contaminant-specific	U.S. EPA 2004
D_e	Effective Diffusivity of absorbing chemical in the epidermis (cm^2/sec)	$(7.1 \times 10^{-6}) / (\sqrt{MW})$	U.S. EPA 2004
I_{sc}	Apparent thickness of stratum corneum (cm)	0.001	U.S. EPA 2004
b,c	Correlation coefficients	Contaminant-specific see User's Guide section 4.9.8	U.S. EPA 2004
L_e	Effective Thickness of the Epidermis (cm)	0.01	U.S. EPA 2004
AT_{res-c}	Averaging time - resident child (days)	365 x ED_{res-c} = 2190	U.S. EPA 1989 (pg. 6-23)
AT_{res-a}	Averaging time - resident adult (days)	365 x ED_{res} = 9490	U.S. EPA 1989 (pg. 6-23)
AT_{res}	Averaging time - resident age adjusted (days)	365 x LT = 25550	U.S. EPA 1989 (pg. 6-23)
AT_{com-a}	Averaging time - composite worker (days)	365 x ED_{com} = 9125 (non-carcinogenic)	U.S. EPA 1989 (pg. 6-23)
AT_{com}	Averaging time - composite worker (days)	365 x LT = 25550 (carcinogenic)	U.S. EPA 1989 (pg. 6-23)
AT_{ind-a}	Averaging time - indoor worker (days)	365 x ED_{ind} = 9125 (non-carcinogenic)	U.S. EPA 1989 (pg. 6-23)
AT_{ind}	Averaging time - indoor worker soil (days)	365 x LT = 25550 (carcinogenic)	U.S. EPA 1989 (pg. 6-23)
AT_{out-a}	Averaging time - outdoor worker (days)	365 x ED_{out} = 9125 (non-carcinogenic)	U.S. EPA 1989 (pg. 6-23)
AT_{out}	Averaging time - outdoor worker (days)	365 x LT = 25550 (carcinogenic)	U.S. EPA 1989 (pg. 6-23)
AT_{con-a}	Averaging time - construction worker (days)	EW_{con} x 7 (d/wk) x ED_{con} = 350 (non-carcinogenic)	U.S. EPA 1989 (pg. 6-23)
AT_{con}	Averaging time - construction worker (days)	365 x LT = 25550 (carcinogenic)	U.S. EPA 1989 (pg. 6-23)
AT_{rec-c}	Averaging time - recreator child (days)	365 x ED_{rec-c}	U.S. EPA 1989 (pg. 6-23)
AT_{rec-a}	Averaging time - recreator adult (days)	365 x ED_{rec-a}	U.S. EPA 1989 (pg. 6-23)
AT_{rec}	Averaging time - recreator (days)	365 x LT	U.S. EPA 1989 (pg. 6-23)
LT	Lifetime (years)	70	U.S. EPA 1989 (pg. 6-22)
$\Delta H_{v,b}$	Enthalpy of vaporization at the normal boiling point (cal/mol)	Contaminant-specific	See Chemical-specific hierarchy
$\Delta H_{v,gw}$	Enthalpy of vaporization at temperature of groundwater (cal/mol)	Contaminant-specific	Determined in this calculator
HLC	Henry's Law Constant at specified groundwater temperature (atm-m^3/mol)	Contaminant-specific	See Chemical-specific hierarchy
T_{gw}	Groundwater Temperatures (Kelvin)	Site-Specific	Site-Specific
T_c	Critical Temperatures (Kelvin)	Contaminant-specific	See Chemical-specific hierarchy
T_b	Normal Boiling Point (Kelvin)	Contaminant-specific	See Chemical-specific hierarchy
n	If (T_{gw}/T_c < 0.57)	n = 0.3	U.S. EPA Fact Sheet
	If (T_{gw}/T_c > 0.71)	n = 0.41	Unitless exponent values used to determine $\Delta H_{v,gw}$

Symbol	Definition (units)	Default	Reference
	Miscellaneous Variables		
	If $(0.57 < T_s/T_c \leq 0.71)$	$n = (0.74 \times T_s/T_c - 0.116)$	
VPT_{gw}	Vapor Pressure at Groundwater Temperature (mmHg)	Contaminant-specific	Determined in this calculator
VP	Vapor Pressure at 25°C (mmHg)	Contaminant-specific	Contaminant-specific

Symbol	Definition (units)	Default	Reference
	Toxicity Values		
RfD_o or RFDOC	Chronic Oral Reference Dose (mg/kg-day)	Contaminant-specific	EPA Superfund hierarchy
RfC or RFCIC	Chronic Inhalation Reference Concentration (mg/m^3)	Contaminant-specific	EPA Superfund hierarchy
$SRfD_o$ or RFDOS	Subhronic Oral Reference Dose (mg/kg-day)	Contaminant-specific	EPA Superfund hierarchy
SRfC or RFCIS	Subchronic Inhalation Reference Concentration (mg/m^3)	Contaminant-specific	EPA Superfund hierarchy
CSF_o or SFO	Oral Slope Factor $(mg/kg\text{-}day)^{-1}$	Contaminant-specific	EPA Superfund hierarchy
IUR	Inhalation Unit Risk $(\mu g/m^3)^{-1}$	Contaminant-specific	EPA Superfund hierarchy

Symbol	Definition (units)	Default	Reference
Ingestion and Dermal Contact Rates			
IRW_{res-c}	Resident Drinking Water Ingestion Rate - Child (L/day)	0.78	U.S. EPA 2011, Tables 3-15 and 3-33; weighted average of 90th percentile consumer-only ingestion of drinking water (birth to <6 years)
IRW_{res-a}	Resident Drinking Water Ingestion Rate - Adult (L/day)	2.5	U.S. EPA 2011, Table 3-33; 90th percentile of consumer-only ingestion of drinking water (>= 21 years)
$IFW_{res-adj}$	Resident Drinking Water Ingestion Rate - Age-adjusted (L/kg)	327.95	Calculated using the age adjusted intake factors equation
$IFWM_{res-adj}$	Resident Mutagenic Drinking Water Ingestion Rate - Age-adjusted (L/kg)	1019.9	Calculated using the age adjusted intake factors equation
IRS_{res-c}	Resident Soil Ingestion Rate - Child (mg/day)	200	U.S. EPA 1991a (pg. 15)
IRS_{res-a}	Resident Soil Ingestion Rate - Adult (mg/day)	100	U.S. EPA 1991a (pg. 15)
$IFS_{res-adj}$	Resident Soil Ingestion Rate - Age-adjusted (mg/kg)	36750	Calculated using the age adjusted intake factors equation
$IFSM_{res-adj}$	Resident Mutagenic Soil Ingestion Rate - Age-adjusted (mg/kg)	166833.33	Calculated using the age adjusted intake factors equation
IR_{ind}	Indoor Worker Soil Ingestion Rate (mg/day)	50	U.S. EPA 1991a (pg. 15)
IR_{out}	Outdoor Worker Soil Ingestion Rate (mg/day)	100	U.S. EPA 1991a (pg. 15)
IR_{con}	Construction Worker Soil Ingestion Rate (mg/day)	330	U.S. EPA 2002 Exhibit 5-1
IR_{com}	Composite Worker Soil Ingestion Rate (mg/day)	100	U.S. EPA 1991a (pg. 15)

	Mechanical Particulate Emission Factor Variables from other than Vehicle Traffic		
PEF'_{sc}	Particulate Emission Factor - subchronic (m^3/kg)	Site-Specific	U.S. EPA 2002 Equation E-26
Q/C_{sa}	Inverse of the ratio of the 1-h. geometric mean air concentration and the emission flux at the center of the square emission source (g/m^2-s per kg/m^3)	Site-Specific	U.S. EPA 2002 Equation E-15
F_D	Dispersion correction factor (unitless)	Site-Specific	U.S. EPA 2002 Equation E-16
A	Dispersion constant unitless	2.4538	U.S. EPA 2002 Equation E-15
B	Dispersion constant unitless	17.566	U.S. EPA 2002 Equation E-15
C	Dispersion constant unitless	189.0426	U.S. EPA 2002 Equation E-15
A_e	Areal extent of site surface soil contamination (acres)	(range 0.5 to 500)	U.S. EPA 2002 Equation E-15
J'_T	Total time-averaged PM_{10} unit emission flux for construction activities other than traffic on unpaved roads (g/m^2-s)	Site-Specific	U.S. EPA 2002 Equation E-25
M^{PC}_{wind}	Unit mass emitted from wind erosion (g)	Site-Specific	U.S. EPA 2002 Equation E-20
V	Fraction of Vegetative Cover (unitless)	0	U.S. EPA 2002 Equation E-20
U_m	Mean Annual Wind Speed (m/s)	4.69	U.S. EPA 2002 Equation E-20
U_t	Equivalent Threshold Value of Wind Speed at 7m (m/s)	11.32	U.S. EPA 2002 Equation E-20
F(x)	Function Dependent on U_m/U_t (unitless)	0.194	U.S. EPA 2002 Equation E-20
A_{surf}	Areal extent of site surface soil contamination (m^2)	(range 0.5 to 500)	U.S. EPA 2002 Equation E-20
ED	Exposure duration (years)	Site-Specific	U.S. EPA 2002 Equation E-20
M_{excav}	Unit mass emitted from excavation soil dumping (g)	Site-Specific	U.S. EPA 2002 Equation E-21
0.35	PM_{10} particle size multiplier (unitless)	0.35	U.S. EPA 2002 Equation E-21
U_m	Mean annual wind speed during construction (m/s)	4.69	U.S. EPA 2002 Equation E-21
$M_{m\text{-}excav}$	Gravimetric soil moisture content (%)	12 (mean value for municipal landfill cover)	U.S. EPA 2002 Equation E-21
ρ_{soil}	In situ soil density (includes water) (mg/m^3)	1.68	U.S. EPA 2002 Equation E-21
A_{excav}	Areal extent of excavation (m^2)	(range 0.5 to 500)	U.S. EPA 2002 Equation E-21
d_{excav}	Average depth of excavation (m)	Site-Specific	U.S. EPA 2002 Equation E-21
$N_{A\text{-}dump}$	Number of times soil is dumped (unitless)	2	U.S. EPA 2002 Equation E-21
M_{doz}	Unit mass emitted from dozing operations (g)	Site-Specific	U.S. EPA 2002 Equation E-22
0.75	PM_{10} scaling factor (unitless)	0.75	U.S. EPA 2002 Equation E-22
s_{doz}	Soil silt content (%)	6.9	U.S. EPA 2002 Equation E-22
$M_{m\text{-}doz}$	Gravimetric soil moisture content (%)	7.9 (mean value for overburden)	U.S. EPA 2002 Equation E-22
$\sum VKT_{doz}$	Sum of dozing kilometers traveled (km)	Site-Specific	U.S. EPA 2002 Equation E-22
S_{doz}	Average dozing speed (kph)	11.4 (mean value for graders)	U.S. EPA 2002 Equation E-22
$N_{A\text{-}doz}$	Number of times site is dozed (unitless)	Site-Specific	U.S. EPA 2002 Equation E-22
B_s	Dozer blade length (m)	Site-Specific	U.S. EPA 2002 Page E-28
M_{grade}	Unit mass emitted from grading operations (g)	Site-Specific	U.S. EPA 2002 Equation E-23
0.6	PM10 scaling factor (unitless)	0.6	U.S. EPA 2002 Equation E-23
$\sum VKT_{grade}$	Sum of grading kilometers traveled (km)		U.S. EPA 2002 Equation E-23
S_{grade}	Average grading speed (kph)	11.4 (mean value for graders)	U.S. EPA 2002 Equation E-23
$N_{A\text{-}grade}$	Number of times site is graded (unitless)	Site-Specific	U.S. EPA 2002 Equation E-23
B_s	Grader blade length (m)	Site-Specific	U.S. EPA 2002 Page E-28
M_{till}	Unit mass emitted from tilling operations (g)	Site-Specific	U.S. EPA 2002 Equation E-24
s_{till}	Soil silt content (%)	18	U.S. EPA 2002 Equation E-24
$A_{c\text{-}till}$	Areal extent of tilling (acres)	Site-Specific	U.S. EPA 2002 Equation E-24
$A_{c\text{-}grade}$	Areal extent of grading (acres)	Site-Specific	Necessary to solve $\sum_{VKT_{grade}}$ in U.S. EPA 2002 Equation E-23
$A_{c\text{-}doz}$	Areal extent of dozinging (acres)	Site-Specific	Necessary to solve $\sum_{VKT_{grade}}$ in U.S. EPA 2002 Equation E-22
$N_{A\text{-}till}$	Number of times soil is tilled (unitless)	2	U.S. EPA 2002 Equation E-24

TOXICOLOGICAL PROFILE FOR ARSENIC

U.S. DEPARTMENT OF HEALTH AND HUMAN SERVICES
Public Health Service
Agency for Toxic Substances and Disease Registry

August 2007

REC 5446

TR 2131

DISCLAIMER

The use of company or product name(s) is for identification only and does not imply endorsement by the Agency for Toxic Substances and Disease Registry.

UPDATE STATEMENT

A Toxicological Profile for Arsenic, Draft for Public Comment was released in September 2005. This edition supersedes any previously released draft or final profile.

Toxicological profiles are revised and republished as necessary. For information regarding the update status of previously released profiles, contact ATSDR at:

Agency for Toxic Substances and Disease Registry
Division of Toxicology and Environmental Medicine/Applied Toxicology Branch
1600 Clifton Road NE
Mailstop F-32
Atlanta, Georgia 30333

FOREWORD

This toxicological profile is prepared in accordance with guidelines developed by the Agency for Toxic Substances and Disease Registry (ATSDR) and the Environmental Protection Agency (EPA). The original guidelines were published in the *Federal Register* on April 17, 1987. Each profile will be revised and republished as necessary.

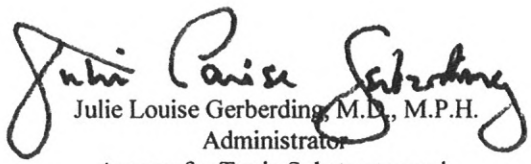
The ATSDR toxicological profile succinctly characterizes the toxicologic and adverse health effects information for the hazardous substance described therein. Each peer-reviewed profile identifies and reviews the key literature that describes a hazardous substance's toxicologic properties. Other pertinent literature is also presented, but is described in less detail than the key studies. The profile is not intended to be an exhaustive document; however, more comprehensive sources of specialty information are referenced.

The focus of the profiles is on health and toxicologic information; therefore, each toxicological profile begins with a public health statement that describes, in nontechnical language, a substance's relevant toxicological properties. Following the public health statement is information concerning levels of significant human exposure and, where known, significant health effects. The adequacy of information to determine a substance's health effects is described in a health effects summary. Data needs that are of significance to protection of public health are identified by ATSDR and EPA.

Each profile includes the following:

(A) The examination, summary, and interpretation of available toxicologic information and epidemiologic evaluations on a hazardous substance to ascertain the levels of significant human exposure for the substance and the associated acute, subacute, and chronic health effects;

(B) A determination of whether adequate information on the health effects of each substance is available or in the process of development to determine levels of exposure that present a significant risk to human health of acute, subacute, and chronic health effects; and



(C) Where appropriate, identification of toxicologic testing needed to identify the types or levels of exposure that may present significant risk of adverse health effects in humans.

The principal audiences for the toxicological profiles are health professionals at the Federal, State, and local levels; interested private sector organizations and groups; and members of the public.

This profile reflects ATSDR's assessment of all relevant toxicologic testing and information that has been peer-reviewed. Staff of the Centers for Disease Control and Prevention and other Federal scientists have also reviewed the profile. In addition, this profile has been peer-reviewed by a nongovernmental panel and is being made available for public review. Final responsibility for the contents and views expressed in this toxicological profile resides with ATSDR.

Howard Frumkin, M.D., Dr. P.H.
Director
National Center for Environmental Health/
Agency for Toxic Substances and
Disease Registry

Julie Louise Gerberding, M.D., M.P.H.
Administrator
Agency for Toxic Substances and
Disease Registry

The toxicological profiles are developed in response to the Superfund Amendments and Reauthorization Act (SARA) of 1986 (Public Law 99-499) which amended the Comprehensive Environmental Response, Compensation, and Liability Act of 1980 (CERCLA or Superfund). This public law directed ATSDR to prepare toxicological profiles for hazardous substances most commonly found at facilities on the CERCLA National Priorities List and that pose the most significant potential threat to human health, as determined by ATSDR and the EPA. The availability of the revised priority list of 275 hazardous substances was announced in the *Federal Register* on December 7, 2005 (70 FR 72840). For prior versions of the list of substances, see *Federal Register* notices dated April 17, 1987 (52 FR 12866); October 20, 1988 (53 FR 41280); October 26, 1989 (54 FR 43619); October 17, 1990 (55 FR 42067); October 17, 1991 (56 FR 52166); October 28, 1992 (57 FR 48801); February 28, 1994 (59 FR 9486); April 29, 1996 (61 FR 18744); November 17, 1997 (62 FR 61332); October 21, 1999 (64 FR 56792); October 25, 2001 (66 FR 54014); and November 7, 2003 (68 FR 63098). Section 104(i)(3) of CERCLA, as amended, directs the Administrator of ATSDR to prepare a toxicological profile for each substance on the list.

QUICK REFERENCE FOR HEALTH CARE PROVIDERS

Toxicological Profiles are a unique compilation of toxicological information on a given hazardous substance. Each profile reflects a comprehensive and extensive evaluation, summary, and interpretation of available toxicologic and epidemiologic information on a substance. Health care providers treating patients potentially exposed to hazardous substances will find the following information helpful for fast answers to often-asked questions.

Primary Chapters/Sections of Interest

Chapter 1: Public Health Statement: The Public Health Statement can be a useful tool for educating patients about possible exposure to a hazardous substance. It explains a substance's relevant toxicologic properties in a nontechnical, question-and-answer format, and it includes a review of the general health effects observed following exposure.

Chapter 2: Relevance to Public Health: The Relevance to Public Health Section evaluates, interprets, and assesses the significance of toxicity data to human health.

Chapter 3: Health Effects: Specific health effects of a given hazardous compound are reported by type of health effect (death, systemic, immunologic, reproductive), by route of exposure, and by length of exposure (acute, intermediate, and chronic). In addition, both human and animal studies are reported in this section.
NOTE: Not all health effects reported in this section are necessarily observed in the clinical setting. Please refer to the Public Health Statement to identify general health effects observed following exposure.

Pediatrics: Four new sections have been added to each Toxicological Profile to address child health issues:

Section 1.6	**How Can (Chemical X) Affect Children?**
Section 1.7	**How Can Families Reduce the Risk of Exposure to (Chemical X)?**
Section 3.7	**Children's Susceptibility**
Section 6.6	**Exposures of Children**

Other Sections of Interest:

Section 3.8	**Biomarkers of Exposure and Effect**
Section 3.11	**Methods for Reducing Toxic Effects**

ATSDR Information Center

Phone: 1-800-CDC-INFO (800-232-4636) or 1-888-232-6348 (TTY) ***Fax:*** (770) 488-4178
E-mail: cdcinfo@cdc.gov ***Internet***: http://www.atsdr.cdc.gov

The following additional material can be ordered through the ATSDR Information Center:

Case Studies in Environmental Medicine: Taking an Exposure History—The importance of taking an exposure history and how to conduct one are described, and an example of a thorough exposure history is provided. Other case studies of interest include *Reproductive and Developmental*

Hazards; Skin Lesions and Environmental Exposures; Cholinesterase-Inhibiting Pesticide Toxicity; and numerous chemical-specific case studies.

Managing Hazardous Materials Incidents is a three-volume set of recommendations for on-scene (prehospital) and hospital medical management of patients exposed during a hazardous materials incident. Volumes I and II are planning guides to assist first responders and hospital emergency department personnel in planning for incidents that involve hazardous materials. Volume III—*Medical Management Guidelines for Acute Chemical Exposures*—is a guide for health care professionals treating patients exposed to hazardous materials.

Fact Sheets (ToxFAQs) provide answers to frequently asked questions about toxic substances.

Other Agencies and Organizations

The National Center for Environmental Health (NCEH) focuses on preventing or controlling disease, injury, and disability related to the interactions between people and their environment outside the workplace. THE PROFILE HAS UNDERGONE THE FOLLOWING ATSDR INTERNAL REVIEWS:

1. Health Effects Review. The Health Effects Review Committee examines the health effects chapter of each profile for consistency and accuracy in interpreting health effects and classifying end points.

2. Minimal Risk Level Review. The Minimal Risk Level Workgroup considers issues relevant to substance-specific Minimal Risk Levels (MRLs), reviews the health effects database of each profile, and makes recommendations for derivation of MRLs.

3. Data Needs Review. The Applied Toxicology Branch reviews data needs sections to assure consistency across profiles and adherence to instructions in the Guidance.

4. Green Border Review. Green Border review assures the consistency with ATSDR policy.

PEER REVIEW

A peer review panel was assembled for arsenic. The panel consisted of the following members:

1. Toby Rossman, Ph.D., Professor of Environmental Medicine, New York University School of Medicine, Nelson Institute of Environmental Medicine, Tuxedo, New York;

2. Rosalind Schoof, Ph.D., DABT, Integral Consulting, Inc., Mercer Island, Washington; and

3. Allan Smith, M.D., Ph.D., Professor of Epidemiology, School of Public Health, University of California, Berkeley, California.

Draft for Public Comment:

1. Alan Hall, M.D., Toxicology Consulting and Medical Translating Services, Inc. (TCMTS, Inc.), Elk Mountain, Wyoming;

2. Gary Pascoe, Ph.D., Pascoe Environmental Consulting, Port Townsend, Washington; and

3. Toby Rossman, Ph.D., Professor of Environmental Medicine, New York University School of Medicine, Nelson Institute of Environmental Medicine, Tuxedo, New York.

These experts collectively have knowledge of arsenic's physical and chemical properties, toxicokinetics, key health end points, mechanisms of action, human and animal exposure, and quantification of risk to humans. All reviewers were selected in conformity with the conditions for peer review specified in Section 104(I)(13) of the Comprehensive Environmental Response, Compensation, and Liability Act, as amended.

Scientists from the Agency for Toxic Substances and Disease Registry (ATSDR) have reviewed the peer reviewers' comments and determined which comments will be included in the profile. A listing of the peer reviewers' comments not incorporated in the profile, with a brief explanation of the rationale for their exclusion, exists as part of the administrative record for this compound.

The citation of the peer review panel should not be understood to imply its approval of the profile's final content. The responsibility for the content of this profile lies with the ATSDR.

1. PUBLIC HEALTH STATEMENT

This public health statement tells you about arsenic and the effects of exposure to it.

The Environmental Protection Agency (EPA) identifies the most serious hazardous waste sites in the nation. These sites are then placed on the National Priorities List (NPL) and are targeted for long-term federal clean-up activities. Arsenic has been found in at least 1,149 of the 1,684 current or former NPL sites. Although the total number of NPL sites evaluated for this substance is not known, the possibility exists that the number of sites at which arsenic is found may increase in the future as more sites are evaluated. This information is important because these sites may be sources of exposure and exposure to this substance may harm you.

When a substance is released either from a large area, such as an industrial plant, or from a container, such as a drum or bottle, it enters the environment. Such a release does not always lead to exposure. You can be exposed to a substance only when you come in contact with it. You may be exposed by breathing, eating, or drinking the substance, or by skin contact.

If you are exposed to arsenic, many factors will determine whether you will be harmed. These factors include the dose (how much), the duration (how long), and how you come in contact with it. You must also consider any other chemicals you are exposed to and your age, sex, diet, family traits, lifestyle, and state of health.

1.1 WHAT IS ARSENIC?

Arsenic is a naturally occurring element that is widely distributed in the Earth's crust. Arsenic is classified chemically as a metalloid, having both properties of a metal and a nonmetal; however, it is frequently referred to as a metal. Elemental arsenic (sometimes referred to as metallic arsenic) is a steel grey solid material. However, arsenic is usually found in the environment combined with other elements such as oxygen, chlorine, and sulfur. Arsenic combined with

these elements is called inorganic arsenic. Arsenic combined with carbon and hydrogen is referred to as organic arsenic.

Most inorganic and organic arsenic compounds are white or colorless powders that do not evaporate. They have no smell, and most have no special taste. Thus, you usually cannot tell if arsenic is present in your food, water, or air.

Inorganic arsenic occurs naturally in soil and in many kinds of rock, especially in minerals and ores that contain copper or lead. When these ores are heated in smelters, most of the arsenic goes up the stack and enters the air as a fine dust. Smelters may collect this dust and take out the arsenic as a compound called arsenic trioxide (As_2O_3). However, arsenic is no longer produced in the United States; all of the arsenic used in the United States is imported.

Presently, about 90% of all arsenic produced is used as a preservative for wood to make it resistant to rotting and decay. The preservative is copper chromated arsenate (CCA) and the treated wood is referred to as "pressure-treated." In 2003, U.S. manufacturers of wood preservatives containing arsenic began a voluntary transition from CCA to other wood preservatives that do not contain arsenic in wood products for certain residential uses, such as play structures, picnic tables, decks, fencing, and boardwalks. This phase out was completed on December 31, 2003; however, wood treated prior to this date could still be used and existing structures made with CCA-treated wood would not be affected. CCA-treated wood products continue to be used in industrial applications. It is not known whether, or to what extent, CCA-treated wood products may contribute to exposure of people to arsenic.

In the past, inorganic arsenic compounds were predominantly used as pesticides, primarily on cotton fields and in orchards. Inorganic arsenic compounds can no longer be used in agriculture. However, organic arsenic compounds, namely cacodylic acid, disodium methylarsenate (DSMA), and monosodium methylarsenate (MSMA), are still used as pesticides, principally on cotton. Some organic arsenic compounds are used as additives in animal feed. Small quantities of elemental arsenic are added to other metals to form metal mixtures or alloys with improved

properties. The greatest use of arsenic in alloys is in lead-acid batteries for automobiles. Another important use of arsenic compounds is in semiconductors and light-emitting diodes.

To learn more about the properties and uses of arsenic, see Chapters 4 and 5.

1.2 WHAT HAPPENS TO ARSENIC WHEN IT ENTERS THE ENVIRONMENT?

Arsenic occurs naturally in soil and minerals and it therefore may enter the air, water, and land from wind-blown dust and may get into water from runoff and leaching. Volcanic eruptions are another source of arsenic. Arsenic is associated with ores containing metals, such as copper and lead. Arsenic may enter the environment during the mining and smelting of these ores. Small amounts of arsenic also may be released into the atmosphere from coal-fired power plants and incinerators because coal and waste products often contain some arsenic.

Arsenic cannot be destroyed in the environment. It can only change its form, or become attached to or separated from particles. It may change its form by reacting with oxygen or other molecules present in air, water, or soil, or by the action of bacteria that live in soil or sediment. Arsenic released from power plants and other combustion processes is usually attached to very small particles. Arsenic contained in wind-borne soil is generally found in larger particles. These particles settle to the ground or are washed out of the air by rain. Arsenic that is attached to very small particles may stay in the air for many days and travel long distances. Many common arsenic compounds can dissolve in water. Thus, arsenic can get into lakes, rivers, or underground water by dissolving in rain or snow or through the discharge of industrial wastes. Some of the arsenic will stick to particles in the water or sediment on the bottom of lakes or rivers, and some will be carried along by the water. Ultimately, most arsenic ends up in the soil or sediment. Although some fish and shellfish take in arsenic, which may build up in tissues, most of this arsenic is in an organic form called arsenobetaine (commonly called "fish arsenic") that is much less harmful.

For more information on how arsenic behaves in the environment, see Chapter 6.

1.3 HOW MIGHT I BE EXPOSED TO ARSENIC?

Since arsenic is found naturally in the environment, you will be exposed to some arsenic by eating food, drinking water, or breathing air. Children may also be exposed to arsenic by eating soil. Analytical methods used by scientists to determine the levels of arsenic in the environment generally do not determine the specific form of arsenic present. Therefore, we do not always know the form of arsenic a person may be exposed to. Similarly, we often do not know what forms of arsenic are present at hazardous waste sites. Some forms of arsenic may be so tightly attached to particles or embedded in minerals that they are not taken up by plants and animals.

The concentration of arsenic in soil varies widely, generally ranging from about 1 to 40 parts of arsenic to a million parts of soil (ppm) with an average level of 3–4 ppm. However, soils in the vicinity of arsenic-rich geological deposits, some mining and smelting sites, or agricultural areas where arsenic pesticides had been applied in the past may contain much higher levels of arsenic. The concentration of arsenic in natural surface and groundwater is generally about 1 part in a billion parts of water (1 ppb), but may exceed 1,000 ppb in contaminated areas or where arsenic levels in soil are high. Groundwater is far more likely to contain high levels of arsenic than surface water. Surveys of U.S. drinking water indicate that about 80% of water supplies have less than 2 ppb of arsenic, but 2% of supplies exceed 20 ppb of arsenic. Levels of arsenic in food range from about 20 to 140 ppb. However, levels of inorganic arsenic, the form of most concern, are far lower. Levels of arsenic in the air generally range from less than 1 to about 2,000 nanograms (1 nanogram equals a billionth of a gram) of arsenic per cubic meter of air (less than 1–2,000 ng/m^3), depending on location, weather conditions, and the level of industrial activity in the area. However, urban areas generally have mean arsenic levels in air ranging from 20 to 30 ng/m^3.

You normally take in small amounts of arsenic in the air you breathe, the water you drink, and the food you eat. Of these, food is usually the largest source of arsenic. The predominant dietary source of arsenic is seafood, followed by rice/rice cereal, mushrooms, and poultry. While seafood contains the greatest amounts of arsenic, for fish and shellfish, this is mostly in an organic form of arsenic called arsenobetaine that is much less harmful. Some seaweeds may

contain arsenic in inorganic forms that may be more harmful. Children are likely to eat small amounts of dust or soil each day, so this is another way they may be exposed to arsenic. The total amount of arsenic you take in from these sources is generally about 50 micrograms (1 microgram equals one-millionth of a gram) each day. The level of inorganic arsenic (the form of most concern) you take in from these sources is generally about 3.5 microgram/day. Children may be exposed to small amounts of arsenic from hand-to-mouth activities from playing on play structures or decks constructed out of CCA-treated wood. The potential exposure that children may receive from playing in play structures constructed from CCA-treated wood is generally smaller than that they would receive from food and water. Hand washing can reduce the potential exposure of children to arsenic after playing on play structures constructed with CCA-treated wood, since most of the arsenic on the children's hands was removed with water.

In addition to the normal levels of arsenic in air, water, soil, and food, you could be exposed to higher levels in several ways, such as the following:

- Some areas of the United States contain unusually high natural levels of arsenic in rock, and this can lead to unusually high levels of arsenic in soil or water. If you live in an area like this, you could take in elevated amounts of arsenic in drinking water. Children may be taking in higher amounts of arsenic because of hand-to-mouth contact or eating soil in areas with higher than usual arsenic concentrations.

- Some hazardous waste sites contain large quantities of arsenic. If the material is not properly disposed of, it can get into surrounding water, air, or soil. If you live near such a site, you could be exposed to elevated levels of arsenic from these media.

- If you work in an occupation that involves arsenic production or use (for example, copper or lead smelting, wood treating, or pesticide application), you could be exposed to elevated levels of arsenic during your work.

- If you saw or sand arsenic-treated wood, you could inhale some of the sawdust into your nose or throat. Similarly, if you burn arsenic-treated wood, you could inhale arsenic in the smoke.

- If you live in a former agricultural area where arsenic was used on crops, the soil could contain high levels of arsenic.

- In the past, several kinds of products used in the home (rat poison, ant poison, weed killer, some types of medicines) had arsenic in them. However, most of these uses of arsenic have ended, so you are not likely to be exposed from home products any longer.

You can find more information on how you may be exposed to arsenic in Chapter 6.

1.4 HOW CAN ARSENIC ENTER AND LEAVE MY BODY?

If you swallow arsenic in water, soil, or food, most of the arsenic may quickly enter into your body. The amount that enters your body will depend on how much you swallow and the kind of arsenic that you swallow. This is the most likely way for you to be exposed near a waste site. If you breathe air that contains arsenic dusts, many of the dust particles settle onto the lining of the lungs. Most of the arsenic in these particles is then taken up from the lungs into the body. You might be exposed in this way near waste sites where arsenic-contaminated soils are allowed to blow into the air, or if you work with arsenic-containing soil or products. If you get arsenic-contaminated soil or water on your skin, only a small amount will go through your skin into your body, so this is usually not of concern.

Both inorganic and organic forms leave your body in your urine. Most of the inorganic arsenic will be gone within several days, although some will remain in your body for several months or even longer. If you are exposed to organic arsenic, most of it will leave your body within several days.

You can find more information on how arsenic enters and leaves your body in Chapter 3.

1.5 HOW CAN ARSENIC AFFECT MY HEALTH?

Scientists use many tests to protect the public from harmful effects of toxic chemicals and to find ways for treating persons who have been harmed.

One way to learn whether a chemical will harm people is to determine how the body absorbs, uses, and releases the chemical. For some chemicals, animal testing may be necessary. Animal testing may also help identify health effects such as cancer or birth defects. Without laboratory animals, scientists would lose a basic method for getting information needed to make wise decisions that protect public health. Scientists have the responsibility to treat research animals with care and compassion. Scientists must comply with strict animal care guidelines because laws today protect the welfare of research animals.

Inorganic arsenic has been recognized as a human poison since ancient times, and large oral doses (above 60,000 ppb in water which is 10,000 times higher than 80% of U.S. drinking water arsenic levels) can result in death. If you swallow lower levels of inorganic arsenic (ranging from about 300 to 30,000 ppb in water; 100–10,000 times higher than most U.S. drinking water levels), you may experience irritation of your stomach and intestines, with symptoms such as stomachache, nausea, vomiting, and diarrhea. Other effects you might experience from swallowing inorganic arsenic include decreased production of red and white blood cells, which may cause fatigue, abnormal heart rhythm, blood-vessel damage resulting in bruising, and impaired nerve function causing a "pins and needles" sensation in your hands and feet.

Perhaps the single-most characteristic effect of long-term oral exposure to inorganic arsenic is a pattern of skin changes. These include patches of darkened skin and the appearance of small "corns" or "warts" on the palms, soles, and torso, and are often associated with changes in the blood vessels of the skin. Skin cancer may also develop. Swallowing arsenic has also been reported to increase the risk of cancer in the liver, bladder, and lungs. The Department of Health and Human Services (DHHS) has determined that inorganic arsenic is known to be a human carcinogen (a chemical that causes cancer). The International Agency for Research on Cancer (IARC) has determined that inorganic arsenic is carcinogenic to humans. EPA also has classified inorganic arsenic as a known human carcinogen.

If you breathe high levels of inorganic arsenic, then you are likely to experience a sore throat and irritated lungs. You may also develop some of the skin effects mentioned above. The exposure level that produces these effects is uncertain, but it is probably above 100 micrograms of arsenic

per cubic meter ($\mu g/m^3$) for a brief exposure. Longer exposure at lower concentrations can lead to skin effects, and also to circulatory and peripheral nervous disorders. There are some data suggesting that inhalation of inorganic arsenic may also interfere with normal fetal development, although this is not certain. An important concern is the ability of inhaled inorganic arsenic to increase the risk of lung cancer. This has been seen mostly in workers exposed to arsenic at smelters, mines, and chemical factories, but also in residents living near smelters and arsenical chemical factories. People who live near waste sites with arsenic may have an increased risk of lung cancer as well.

If you have direct skin contact with high concentrations of inorganic arsenic compounds, your skin may become irritated, with some redness and swelling. However, it does not appear that skin contact is likely to lead to any serious internal effects.

Almost no information is available on the effects of organic arsenic compounds in humans. Studies in animals show that most simple organic arsenic compounds (such as methyl and dimethyl compounds) are less toxic than the inorganic forms. In animals, ingestion of methyl compounds can result in diarrhea, and lifetime exposure can damage the kidneys. Lifetime exposure to dimethyl compounds can damage the urinary bladder and the kidneys.

You can find more information on the health effects of inorganic and organic arsenic in Chapters 2 and 3.

1.6 HOW CAN ARSENIC AFFECT CHILDREN?

This section discusses potential health effects in humans from exposures during the period from conception to maturity at 18 years of age.

Children are exposed to arsenic in many of the same ways that adults are. Since arsenic is found in the soil, water, food, and air, children may take in arsenic in the air they breathe, the water they drink, and the food they eat. Since children tend to eat or drink less of a variety of foods and beverages than do adults, ingestion of contaminated food or juice or infant formula made

with arsenic-contaminated water may represent a significant source of exposure. In addition, since children often play in the soil and put their hands in their mouths and sometimes intentionally eat soil, ingestion of contaminated soil may be a more important source of arsenic exposure for children than for adults. In areas of the United States where natural levels of arsenic in the soil and water are high, or in areas in and around contaminated waste sites, exposure of children to arsenic through ingestion of soil and water may be significant. In addition, contact with adults who are wearing clothes contaminated with arsenic (e.g., with dust from copper- or lead-smelting factories, from wood-treating or pesticide application, or from arsenic-treated wood) could be a source of exposure. Because of the tendency of children to taste things that they find, accidental poisoning from ingestion of pesticides is also a possibility. Thus, although most of the exposure pathways for children are the same as those for adults, children may be at a higher risk of exposure because of normal hand-to-mouth activity.

Children who are exposed to inorganic arsenic may have many of the same effects as adults, including irritation of the stomach and intestines, blood vessel damage, skin changes, and reduced nerve function. Thus, all health effects observed in adults are of potential concern in children. There is also some evidence that suggests that long-term exposure to inorganic arsenic in children may result in lower IQ scores. We do not know if absorption of inorganic arsenic from the gut in children differs from adults. There is some evidence that exposure to arsenic in early life (including gestation and early childhood) may increase mortality in young adults.

There is some evidence that inhaled or ingested inorganic arsenic can injure pregnant women or their unborn babies, although the studies are not definitive. Studies in animals show that large doses of inorganic arsenic that cause illness in pregnant females can also cause low birth weight, fetal malformations, and even fetal death. Arsenic can cross the placenta and has been found in fetal tissues. Arsenic is found at low levels in breast milk.

In animals, exposure to organic arsenic compounds can cause low birth weight, fetal malformations, and fetal deaths. The dose levels that cause these effects also result in effects in the mothers.

You can find more information about how arsenic can affect children in Sections 3.7 and 6.6.

1.7 HOW CAN FAMILIES REDUCE THE RISK OF EXPOSURE TO ARSENIC?

If your doctor finds that you have been exposed to substantial amounts of arsenic, ask whether your children might also have been exposed. Your doctor might need to ask your state health department to investigate.

Many communities may have high levels of arsenic in their drinking water, particularly from private wells, because of contamination or as a result of the geology of the area. The north central region and the western region of the United States have the highest arsenic levels in surface water and groundwater sources, respectively. Wells used to provide water for drinking and cooking should be tested for arsenic. As of January 2006, EPA's Maximum Contaminant Level (MCL) for arsenic in drinking water is 10 ppb. If you have arsenic in your drinking water at levels higher that the EPA's MCL, an alternative source of water should be used for drinking and cooking should be considered.

If you use arsenic-treated wood in home projects, personal protection from exposure to arsenic-containing sawdust may be helpful in limiting exposure of family members. These measures may include dust masks, gloves, and protective clothing. Arsenic-treated wood should never be burned in open fires, or in stoves, residential boilers, or fire places, and should not be composted or used as mulch. EPA's Consumer Awareness Program (CAP) for CCA is a voluntary program established by the manufacturers of CCA products to inform consumers about the proper handling, use, and disposal of CCA-treated wood. You can find more information about this program in Section 6.5. Hand washing can reduce the potential exposure of children to arsenic after playing on play structures constructed with CCA-treated wood, since most of the arsenic on the children's hands was removed with water.

If you live in an area with a high level of arsenic in the water or soil, substituting cleaner sources of water and limiting contact with soil (for example, through use of a dense groundcover or thick lawn) would reduce family exposure to arsenic. By paying careful attention to dust and soil

control in the home (air filters, frequent cleaning), you can reduce family exposure to contaminated soil. Some children eat a lot of soil. You should prevent your children from eating soil. You should discourage your children from putting objects in their mouths. Make sure they wash their hands frequently and before eating. Discourage your children from putting their hands in their mouths or engaging in other hand-to-mouth activities. Since arsenic may be found in the home as a pesticide, household chemicals containing arsenic should be stored out of reach of young children to prevent accidental poisonings. Always store household chemicals in their original labeled containers; never store household chemicals in containers that children would find attractive to eat or drink from, such as old soda bottles. Keep your Poison Control Center's number by the phone.

It is sometimes possible to carry arsenic from work on your clothing, skin, hair, tools, or other objects removed from the workplace. This is particularly likely if you work in the fertilizer, pesticide, glass, or copper/lead smelting industries. You may contaminate your car, home, or other locations outside work where children might be exposed to arsenic. You should know about this possibility if you work with arsenic.

Your occupational health and safety officer at work can and should tell you whether chemicals you work with are dangerous and likely to be carried home on your clothes, body, or tools and whether you should be showering and changing clothes before you leave work, storing your street clothes in a separate area of the workplace, or laundering your work clothes at home separately from other clothes. Material safety data sheets (MSDS) for many chemicals used should be found at your place of work, as required by the Occupational Safety and Health Administration (OSHA) in the U.S. Department of Labor. MSDS information should include chemical names and hazardous ingredients, and important properties, such as fire and explosion data, potential health effects, how you get the chemical(s) in your body, how to properly handle the materials, and what to do in the case of emergencies. Your employer is legally responsible for providing a safe workplace and should freely answer your questions about hazardous chemicals. Your state OSHA-approved occupational safety and health program or OSHA can answer any further questions and help your employer identify and correct problems with hazardous substances. Your state OSHA-approved occupational safety and health program or

OSHA will listen to your formal complaints about workplace health hazards and inspect your workplace when necessary. Employees have a right to seek safety and health on the job without fear of punishment.

You can find more information about how arsenic can affect children in Sections 3.7 and 6.6.

1.8 IS THERE A MEDICAL TEST TO DETERMINE WHETHER I HAVE BEEN EXPOSED TO ARSENIC?

Several sensitive and specific tests can measure arsenic in your blood, urine, hair, or fingernails, and these tests are often helpful in determining if you have been exposed to above-average levels of arsenic in the past. These tests are not usually performed in a doctor's office. They require sending the sample to a testing laboratory.

Measurement of arsenic in your urine is the most reliable means of detecting arsenic exposures that you experienced within the last several days. Most tests measure the total amount of arsenic present in your urine. This can sometimes be misleading, because the nonharmful forms of arsenic in fish and shellfish can give a high reading even if you have not been exposed to a toxic form of arsenic. For this reason, laboratories sometimes use a more complicated test to separate "fish arsenic" from other forms. Because most arsenic leaves your body within a few days, analysis of your urine cannot detect if you were exposed to arsenic in the past. Tests of your hair or fingernails can tell if you were exposed to high levels over the past 6–12 months, but these tests are not very useful in detecting low-level exposures. If high levels of arsenic are detected, this shows that you have been exposed, but unless more is known about when you were exposed and for how long, it is usually not possible to predict whether you will have any harmful health effects.

You can find more information on how arsenic can be measured in your hair, urine, nails, and other tissues in Chapters 3 and 7.

1.9 WHAT RECOMMENDATIONS HAS THE FEDERAL GOVERNMENT MADE TO PROTECT HUMAN HEALTH?

The federal government develops regulations and recommendations to protect public health. Regulations *can* be enforced by law. The EPA, the Occupational Safety and Health Administration (OSHA), and the Food and Drug Administration (FDA) are some federal agencies that develop regulations for toxic substances. Recommendations provide valuable guidelines to protect public health, but *cannot* be enforced by law. The Agency for Toxic Substances and Disease Registry (ATSDR) and the National Institute for Occupational Safety and Health (NIOSH) are two federal organizations that develop recommendations for toxic substances.

Regulations and recommendations can be expressed as "not-to-exceed" levels, that is, levels of a toxic substance in air, water, soil, or food that do not exceed a critical value that is usually based on levels that affect animals; they are then adjusted to levels that will help protect humans. Sometimes these not-to-exceed levels differ among federal organizations because they used different exposure times (an 8-hour workday or a 24-hour day), different animal studies, or other factors.

Recommendations and regulations are also updated periodically as more information becomes available. For the most current information, check with the federal agency or organization that provides it. Some regulations and recommendations for ARSENIC include the following:

The federal government has taken several steps to protect humans from arsenic. First, EPA has set limits on the amount of arsenic that industrial sources can release into the environment. Second, EPA has restricted or canceled many of the uses of arsenic in pesticides and is considering further restrictions. Third, in January 2001, the EPA lowered the limit for arsenic in drinking water from 50 to 10 ppb. Finally, OSHA has established a permissible exposure limit (PEL), 8-hour time-weighted average, of 10 $\mu g/m^3$ for airborne arsenic in various workplaces that use inorganic arsenic.

You can find more information on regulations and guidelines that apply to arsenic in Chapter 8.

1.10 WHERE CAN I GET MORE INFORMATION?

If you have any more questions or concerns, please contact your community or state health or environmental quality department, or contact ATSDR at the address and phone number below.

ATSDR can also tell you the location of occupational and environmental health clinics. These clinics specialize in recognizing, evaluating, and treating illnesses that result from exposure to hazardous substances.

Toxicological profiles are also available on-line at www.atsdr.cdc.gov and on CD-ROM. You may request a copy of the ATSDR ToxProfiles™ CD-ROM by calling the toll-free information and technical assistance number at 1-800-CDCINFO (1-800-232-4636), by e-mail at cdcinfo@cdc.gov, or by writing to:

Agency for Toxic Substances and Disease Registry
Division of Toxicology and Environmental Medicine
1600 Clifton Road NE
Mailstop F-32
Atlanta, GA 30333
Fax: 1-770-488-4178

Organizations for-profit may request copies of final Toxicological Profiles from the following:

National Technical Information Service (NTIS)

2. RELEVANCE TO PUBLIC HEALTH

2.1 BACKGROUND AND ENVIRONMENTAL EXPOSURES TO ARSENIC IN THE UNITED STATES

Arsenic is widely distributed in the Earth's crust, which contains ~3.4 ppm arsenic. In nature, arsenic is mostly found in minerals and only to a small extent in its elemental form. Arsenic is mainly obtained as a byproduct of the smelting of copper, lead, cobalt, and gold ores. Arsenic trioxide is the primary form in which arsenic is marketed and consumed. There has been no domestic production of arsenic since 1985. In 2003, the world's largest producer of arsenic compounds was China, followed by Chile and Peru.

In 2003, the United States was the world's largest consumer of arsenic. Production of wood preservatives, primarily copper chromated arsenate (CCA), $CrO_3 \cdot CuO \cdot As_2O_5$, accounted for >90% of domestic consumption of arsenic trioxide. In response to consumer concerns, U.S. manufacturers of arsenical wood preservative began a voluntary transition from CCA to other wood preservatives for certain residential wood products. This phase-out was completed on December 31, 2003; wood treated prior to this date could still be used and CCA-treated wood products continue to be used in industrial applications.

Other uses for arsenic compounds include the production of agricultural chemicals, as an alloying element in ammunition and solders, as an anti-friction additive to metals used for bearings, and to strengthen lead-acid storage battery grids. High-purity arsenic (99.9999%) is used by the electronics industry for gallium-arsenide semiconductors for telecommunications, solar cells, and space research. Various organic arsenicals are still used in the United States as herbicides and as antimicrobial additives for animal and poultry feed. However, the use of inorganic arsenic compounds in agriculture has virtually disappeared beginning around the 1960s. Arsenic trioxide and arsenic acid were used as a decolorizer and fining agent in the production of bottle glass and other glassware. Arsenic compounds also have a long history of use in medicine, and have shown a re-emergence of late with the recent introduction of arsenic trioxide treatment for acute promyelocytic leukemia.

The principal route of exposure to arsenic for the general population is likely to be the oral route, primarily in the food and in the drinking water. Dietary exposures to total arsenic were highly variable, with a mean of 50.6 µg/day (range of 1.01–1,081 µg/day) for females and 58.5 µg/day (range of 0.21–1,276 µg/day) for males. U.S. dietary intake of inorganic arsenic has been estimated to range from 1 to 20 µg/day, with grains and produce expected to be significant contributors to dietary inorganic arsenic

intake. Drinking water generally contains an average of 2 µg/L of arsenic, although 12% of water supplies from surface water sources in the North Central region of the country and 12% of supplies from groundwater sources in the Western region have levels exceeding 20 µg/L. Arsenic is also widely distributed in surface water, groundwater, and finished drinking water in the United States. Surveys of arsenic concentrations in rivers and lakes indicate that most values are below 10 µg/L, although individual samples may range up to 3,400 µg/L. Arsenic released to the land at hazardous waste sites is likely to be relatively immobile due to a high capacity for soil binding, particularly to iron and manganese oxides. Exposure to arsenic from other pathways is generally small, but may be significant for areas with high levels of arsenic contamination or in occupational settings. For a more complete discussion of possible exposures to arsenic, see Chapter 6 of the profile.

2.2 SUMMARY OF HEALTH EFFECTS

Arsenic is a potent toxicant that may exist in several oxidation states and in a number of inorganic and organic forms. Most cases of arsenic-induced toxicity in humans are due to exposure to inorganic arsenic, and there is an extensive database on the human health effects of the common arsenic oxides and oxyacids. Although there may be some differences in the potency of different chemical forms (e.g., arsenites tend to be somewhat more toxic than arsenates), these differences are usually minor. An exception would be arsine, which is highly toxic. However, because arsine and its methyl derivatives are gases or volatile liquids and are unlikely to be present at levels of concern at hazardous waste sites, health effect data for these compounds are not discussed in this document. Humans may be exposed to organic arsenicals (mainly methyl and phenyl derivatives of arsenic acid) that are used in agriculture and to organic arsenicals found in fish and shellfish (arsenobetaine and arsenocholine). Although the toxicity of organic arsenicals has not been as extensively investigated as inorganic arsenicals, there are sufficient animal data to evaluate the toxicity of methyl arsenates (e.g., monomethylarsonic acid [MMA] and dimethylarsinic acid [DMA]) and roxarsone. The so-called "fish arsenic" compounds (e.g., arsenobetaine) are not thought to be toxic and health effects data are not discussed in this document.

It is generally accepted that the arsenic-carbon bond is quite strong and most mammalian species do not have the capacity to break this bond; thus, inorganic arsenic is not formed during the metabolism of organic arsenicals. In most species, including humans, ingested (or exogenous) MMA(V) and DMA(V) undergo limited metabolism, do not readily enter the cell, and are primarily excreted unchanged in the urine. This is in contrast to inorganic arsenic, which undergoes sequential reduction and methylation reactions leading to the formation of MMA and DMA. Inorganic As(V) is readily reduced to inorganic

As(III), which is taken up by the cell. Within the cell (primarily in the liver), As(III) is methylated to form MMA(V), which is reduced to MMA(III); MMA(III) subsequently undergoes oxidative methylations to form DMA(V). DMA(V) is the primary excretion product in humans. Because inorganic and organic arsenicals exhibit distinct toxicokinetic characteristics, the health effects and MRLs are considered separately.

Inorganic Arsenicals. Exposures of humans near hazardous waste sites could involve inhalation of arsenic dusts in air, ingestion of arsenic in water, food, or soil, or dermal contact with contaminated soil or water. Increased risk of lung cancer, respiratory irritation, nausea, skin effects, and neurological effects have been reported following inhalation exposure. There are only a few quantitative data on noncancer effects in humans exposed to inorganic arsenic by the inhalation route. Animal data similarly identify effects on the respiratory system as the primary noncancer effect of inhaled inorganic arsenic compounds, although only a few studies are available. Only limited data on the effects of inhaled organic arsenic compounds in humans or animals are available; these studies are generally limited to high-dose, short-term exposures, which result in frank effects.

Relatively little information is available on effects due to direct dermal contact with inorganic arsenicals, but several studies indicate that the chief effect is local irritation and dermatitis, with little risk of other adverse effects.

The database for the oral toxicity of inorganic arsenic is extensive, containing a large number of studies of orally-exposed human populations. These studies have identified effects on virtually every organ or tissue evaluated, although some end points appear to be more sensitive than others. The available data from humans identify the skin as the most sensitive noncancer target following long-term oral arsenic exposure. Typical dermal effects include hyperkeratinization of the skin (especially on the palms and soles), formation of multiple hyperkeratinized corns or warts, and hyperpigmentation of the skin with interspersed spots of hypopigmentation. Oral exposure data from studies in humans indicate that these lesions typically begin to manifest at exposure levels of about 0.002–0.02 mg As/kg/day, but one study suggests that lesions may appear at even lower levels. At these exposure levels, peripheral vascular effects are also commonly noted, including cyanosis, gangrene, and, in Taiwanese populations, the condition known as "Blackfoot Disease." Other reported cardiovascular effects of oral exposure to inorganic arsenic include increased incidences of high blood pressure and circulatory problems. The use of intravenous arsenic trioxide as therapy for acute promyelocytic leukemia has raised further concerns about the cardiovascular effects of arsenic, including alterations in cardiac QT interval and the

development of torsades de pointes. Decrements in lung function, assessed by spirometry, have been reported in subjects exposed to approximately 0.008–0.04 mg As/kg/day in the drinking water who exhibited skin lesions.

In addition to dermal, cardiovascular, and respiratory effects, oral exposure to inorganic arsenic may result in effects on other organ systems. Nausea, vomiting, and diarrhea are very common symptoms in humans following oral exposure to inorganic arsenicals, both after acute high-dose exposure and after repeated exposure to lower doses; these effects are likely due to a direct irritation of the gastrointestinal mucosa. Acute, high-dose exposure can lead to encephalopathy, with clinical signs such as confusion, hallucinations, impaired memory, and emotional lability, while long-term exposure to lower levels can lead to the development of peripheral neuropathy characterized by a numbness in the hands and feet that may progress to a painful "pins and needles" sensation. Recent studies also have reported neurobehavioral alterations in arsenic-exposed children.

Chronic exposure of humans to inorganic arsenic in the drinking water has been associated with excess incidence of miscarriages, stillbirths, preterm births, and infants with low birth weights. Animal data suggest that arsenic may cause changes to reproductive organs of both sexes, including decreased organ weight and increased inflammation of reproductive tissues, although these changes may be secondary effects. However, these changes do not result in a significant impact on reproductive ability. Animal studies of oral inorganic arsenic exposure have reported developmental effects, but generally only at concentrations that also resulted in maternal toxicity.

Arsenic is a known human carcinogen by both the inhalation and oral exposure routes. By the inhalation route, the primary tumor types are respiratory system cancers, although a few reports have noted increased incidence of tumors at other sites, including the liver, skin, and digestive tract. In humans exposed chronically by the oral route, skin tumors are the most common type of cancer. In addition to skin cancer, there are a number of case reports and epidemiological studies that indicate that ingestion of arsenic also increases the risk of internal tumors (mainly of bladder and lung, and to a lesser extent, liver, kidney, and prostate).

The Department of Health and Human Services (DHHS) has concluded that inorganic arsenic is known to be a human carcinogen. The International Agency for Research on Cancer (IARC) cites sufficient evidence of a relationship between exposure to arsenic and human cancer. The IARC classification of arsenic is Group 1. The EPA has determined that inorganic arsenic is a human carcinogen by the

inhalation and oral routes, and has assigned it the cancer classification, Group A. EPA has calculated an oral cancer slope factor of 1.5 $(mg/kg/day)^{-1}$ and a drinking water unit risk of $5x10^{-5}$ $(\mu g/L)^{-1}$ for inorganic arsenic based on human dose-response data. The inhalation unit risk for cancer is calculated to be 0.0043 $(\mu g/m^3)^{-1}$. The unit risk is the upper-bound excess lifetime cancer risk estimated to result from continuous exposure to an agent at a concentration of 1 µg/L in water or 1 $\mu g/m^3$ in air. EPA is currently revising the assessment for inorganic arsenic; a more detailed discussion of the uncertainties associated with human cancer risk levels for arsenic is presented in Section 3.2.2.7.

The following sections discuss significant effects resulting from exposure to inorganic arsenic in greater detail: dermal, cardiovascular, respiratory, gastrointestinal, neurological, and cancer. Additional information on these effects and on other effects is discussed in Section 3.2.

Dermal Effects. The most characteristic effect of long-term oral exposure to inorganic arsenic compounds is the development of skin lesions; these lesions are often used as diagnostic criteria for arsenicosis. The three lesions most often associated with chronic arsenicosis are hyperkeratinization of the skin (especially on the palms and soles), formation of multiple hyperkeratinized corns or warts, and hyperpigmentation of the skin with interspersed spots of hypopigmentation. Numerous studies of long-term, low-level exposure to inorganic arsenic in humans have reported the presence of these lesions. In general, they begin to manifest at chronic exposure levels >0.02 mg As/kg/day. Chronic oral studies of lower exposure levels, ranging from 0.0004 to 0.01 mg As/kg/day, have generally not reported dermal effects. However, in a study with detailed exposure assessment, all confirmed cases of skin lesions ingested water containing >100 µg/L arsenic (approximately 0.0037 mg As/kg/day) and the lowest known peak arsenic concentration ingested by a case was 0.115 µg/L (approximately 0.0043 mg As/kg/day). Another large study reported increased incidence of skin lesions associated with estimated doses of 0.0012 mg As/kg/day (0.023 mg As/L drinking water). The mechanism(s) by which inorganic arsenic causes dermal effects is not well-understood. Elucidating the mechanism of dermal effects has been particularly difficult because the dermal effects common in humans have not been seen in studies in animals.

Dermal effects have also been reported following inhalation exposures to inorganic arsenic, although they are not as diagnostic as for oral exposure. Several studies of arsenic-exposed workers have reported the development of dermatitis; exposure levels required to produce this condition are not well-established. Altered dermal pigmentation and hyperkeratosis have also been reported in studies of humans exposed to inorganic arsenic by inhalation, although exposure levels have varied considerably. Direct dermal contact

with inorganic arsenicals may cause irritation and contact dermatitis. Usually, the effects are mild (erythema and swelling), but may progress to papules, vesicles, or necrotic lesions in extreme cases; these conditions tend to heal without treatment if exposure ceases.

Cardiovascular Effects. A large number of studies in humans have reported cardiovascular effects following oral exposure to inorganic arsenic compounds. The cardiac effects of arsenic exposure are numerous, and include altered myocardial depolarization (prolonged QT interval, nonspecific ST segment changes), cardiac arrhythmias, and ischemic heart disease. These effects have been seen after acute and long-term exposure to inorganic arsenic in the environment, as well as side effects from intravenous therapy with arsenic trioxide for acute promyelocytic leukemia. Exposure levels for environmental exposures have not been well characterized, but intravenous doses for arsenic trioxide therapy are generally on the order of 0.15 mg As/kg/day.

Chronic exposure to inorganic arsenic has also been shown to lead to effects on the vascular system. The most dramatic of these effects is "Blackfoot Disease," a disease characterized by a progressive loss of circulation in the hands and feet, leading ultimately to necrosis and gangrene. Blackfoot Disease is endemic in an area of Taiwan where average drinking water levels of arsenic range from 0.17 to 0.80 ppm, corresponding to doses of about 0.014–0.065 mg As/kg/day. The results of a another study suggested that individuals with a lower capacity to methylate inorganic arsenic to DMA have a higher risk of developing peripheral vascular disease in the Blackfoot Disease-hyperendemic area in Taiwan. Arsenic exposure in Taiwan has also been associated with an increased incidence of cerebrovascular and microvascular diseases and ischemic heart disease. While Blackfoot Disease itself has not been reported outside of Taiwan, other vascular effects are common in areas with high arsenic exposures, and include such severe effects as increases in the incidences of Raynaud's disease and of cyanosis of fingers and toes as well as hypertension, thickening and vascular occlusion of blood vessels, and other unspecified cardiovascular conditions. However, while the majority of human studies have reported cardiovascular effects following exposure to inorganic arsenic, some have found no such effects.

Changes in cardiac rhythm and in some vascular end points have also been reported in animal studies of inorganic arsenicals, but generally only at higher exposure levels and not to the degree of severity seen in humans.

Respiratory Effects. While case reports and small cohort studies have routinely reported an increase in respiratory symptoms of humans exposed occupationally to inorganic arsenic, dose-response data for

these symptoms are generally lacking. The only study that evaluated respiratory effects (changes in chest x-ray or respiratory performance) and reported an exposure estimate did not report significant changes at an exposure level of 0.613 mg As/m^3. Exposed workers often report irritation of the mucous membranes of the nose and throat, which may lead to laryngitis, bronchitis, or rhinitis. Increased mortality due to respiratory disease has been reported in some cohort mortality studies of arsenic-exposed workers, but no conclusive evidence of an association of these diseases with arsenic exposure has been presented. It is not known whether respiratory effects following inhaled inorganic arsenic compounds are due to a direct effect of arsenic on respiratory tissues, general effects of foreign material in the lungs, or an effect of arsenic on the pulmonary vasculature. Similar responses, including rales, labored breathing, and respiratory hyperplasia, have been noted in animal studies of inhaled or instilled inorganic arsenic compounds.

Respiratory effects have also been reported following oral exposure of humans to inorganic arsenic. Acute oral exposure to ≥8 mg As/kg may result in serious respiratory effects, including respiratory distress, hemorrhagic bronchitis, and pulmonary edema; however, it is not clear whether these are primary effects or are the result of damage to the pulmonary vascular system. In general, respiratory effects have not been widely associated with long-term oral exposure to low arsenic doses. However, some studies have reported minor respiratory symptoms, such as cough, sputum, rhinorrhea, and sore throat, in people with repeated oral exposure to 0.03–0.05 mg As/kg/day. More serious respiratory effects, such as bronchitis and sequelae (bronchiectasis, bronchopneumonia) have been observed in patients chronically exposed to arsenic and at autopsy in some chronic poisoning cases. There are few animal data reporting respiratory effects of oral exposure to inorganic arsenic, and those studies generally found effects only at very high dose levels.

Gastrointestinal Effects. Both short-term and chronic oral exposures to inorganic arsenicals have been reported to result in irritant effects on gastrointestinal tissues. Numerous studies of acute, high-dose exposure to inorganic arsenicals have reported nausea, vomiting, diarrhea, and abdominal pain, although specific dose levels associated with the onset of these symptoms have not been identified. Chronic oral exposure to 0.01 mg As/kg/day generally results in similar reported symptoms. For both acute and chronic exposures, the gastrointestinal effects generally diminish or resolve with cessation of exposure. Similar gastrointestinal effects have been reported after occupational exposures to inorganic arsenicals, although it is not known if these effects were due to absorption of arsenic from the respiratory tract or from mucociliary clearance resulting in eventual oral exposure.

Neurological Effects. A common effect following both oral and inhalation exposure to inorganic is the development of peripheral neuropathy. Following occupational exposure to inorganic arsenic in pesticide plants or smelters, exposed workers have shown increased incidence of neurological changes, including altered nerve conduction velocities. One study reported that these effects were seen after 28 years of exposure to 0.31 mg As/m^3. In another study, signs and symptoms of sensory and motor polyneuropathy on both upper and lower extremities were reported in workers at a power station in Slovakia. The average length of exposure was 22.3 years (standard deviation [SD] ±8.4 years) and the average arsenic exposure in inhaled air ranged from 4.6 to 142.7 µg/m^3.

Following high-dose (>2 mg As/kg/day) acute oral exposures to inorganic arsenicals in humans, reported effects include headache, lethargy, mental confusion, hallucination, seizures, and coma. Following longer-term exposure to 0.03–0.1 mg As/kg/day, peripheral neuropathy, characterized initially by numbness of the hands and feet and a "pins and needles" sensation and progressing to muscle weakness, wrist-drop and/or ankle-drop, diminished sensitivity, and altered reflex action. Histological features of the neuropathy include a dying-back axonopathy and demyelination. Following removal from exposure, the neuropathy is only partially reversible and what recovery does occur is generally slow. Reports of neurological effects at lower arsenic levels (0.004–0.006 mg As/kg/day) have been inconsistent, with some human studies reporting fatigue, headache, depression, dizziness, insomnia, nightmare, and numbness while others reported no neurological effects. Some studies also have reported that exposure to arsenic may be associated with intellectual deficits in children. Neurological effects have also been reported in oral studies of arsenic toxicity in animals, although these were generally performed at higher doses (0.4–26.6 mg As/kg/day) than has been reported in exposed human populations. The mechanism(s) of arsenic-induced neurological changes has not been determined.

Cancer. There is clear evidence from studies in humans that exposure to inorganic arsenic by either the inhalation or oral routes increases the risk of cancer. Numerous studies of copper smelters or miners exposed to arsenic trioxide have reported an increased risk of lung cancer. Increased incidence of lung cancer has also been observed at chemical plants where exposure was primarily to arsenate. Other studies suggest that residents living near smelters or arsenical chemical plants may have increased risk of lung cancer, although the reported increases are small and are not clearly detectable in all cases. In general, studies reporting long-term exposure to 0.07 mg As/m^3 or greater have shown an increased incidence of lung cancer, while at lower exposure levels, the association has been less clear or not present.

There is convincing evidence from a large number of epidemiological studies and case reports that ingestion of inorganic arsenic increases the risk of developing skin cancer. The most common tumors seen are squamous cell carcinomas, which may develop from the hyperkeratotic warts or corns commonly seen as a dermal effect of oral inorganic arsenic exposure. Early studies of populations within the United States did not suggest an increased risk of cancer from oral inorganic arsenic exposure. Later studies have found suggestive evidence that the possibility of arsenic-induced skin cancers cannot be discounted based on an association between toenail arsenic levels and incidence of skin cancer.

There is increasing evidence that long-term exposure to arsenic can result in the development of bladder cancer, with transitional cell cancers being the most prevalent. While studies have noted statistical dose-response trends in arsenic-induced bladder cancers, reliable quantitative assessments of dose-response relationships have not been presented. Several studies have also shown that chronic oral exposure to arsenic results in the development of respiratory tumors, making lung cancer an established cause of death from exposure to arsenic in drinking water. Exposure levels in studies evaluating respiratory and bladder cancers have been comparable to those in studies evaluating skin tumors. Studies of U.S. populations have not identified an increased risk of bladder or respiratory tumors following oral exposure to inorganic arsenic.

Animal studies of both inhalation and oral exposure to inorganic arsenicals have not resulted in increased incidence of cancer formation in adult animals. However, a series of studies have shown that inorganic arsenic can induce cancer in the offspring from mice exposed to arsenic during gestation (transplacental carcinogen) and acts as a co-carcinogen with UV light and polycyclic aromatic hydrocarbons (PAHs).

Organic Arsenicals. Humans may be exposed to organic arsenicals via inhalation of dusts, ingestion of organic arsenic in water, food, soil, or dermal contact with contaminated soil, water or plants following pesticide application. There are limited data on the toxicity of organic arsenicals following inhalation exposure in humans and animals and these data do not allow for identification of critical effects. Keratosis was observed in workers exposed to 0.065 mg/m^3 arsanilic acid (i.e., 4-aminophenyl arsenic acid); no alterations in gastrointestinal symptoms or hematological alterations were observed. In animals, very high concentrations (>3,000 mg/m^3) of DMA results in respiratory distress, diarrhea, and erythematous lesions on the feet and ears. No adverse effects were observed in rats exposed to DMA concentrations as high as 100 mg DMA/m^3 for 95 days.

Similarly, the available dermal toxicity data do not allow for identification of critical effects. Contact dermatitis was observed in workers applying DMA (and its sodium salt) and mild dermal irritation was observed in a Draize test in rabbits (adverse effect level not reported). Intermediate duration (21 days) exposure studies in rabbits did not result in systemic toxicity or skin irritation following 5 day/week exposure to 1,000 mg/kg/day MMA or DMA.

The preponderance of toxicity data for organic arsenicals involves oral exposure. Human data are limited to three case reports of individuals intentionally ingesting pesticides containing organic arsenicals. Gastrointestinal irritation (vomiting, nausea, and diarrhea) were consistently reported in these cases. Animal data has primarily focused on the toxicity of MMA, DMA, and roxarsone; these data suggest that the targets of toxicity may differ between the compounds.

MMA. The gastrointestinal tract appears to be the most sensitive target of toxicity for MMA. Diarrhea and tissue damage in the large intestine have been reported in several animal species following dietary, gavage, and capsule exposure. For diarrhea, both the time of onset and incidence appear to be dose-related. In rats, diarrhea was observed in 100% of females exposed to 98.5 mg MMA/kg/day, 55% of females exposed to 33.9 mg MMA/kg/day, and 5.1% of females exposed to 3.9 mg MMA/kg/day. The increased incidence of diarrhea was observed after 3 weeks of exposure to 98.5 mg MMA/kg/day, 4 weeks at 33.9 mg MMA/kg/day, and 18 months at 3.9 mg MMA/kg/day. Histological damage consisting of squamous metaplasia of the epithelial columnar absorptive cells in the cecum, colon, and rectum was observed in rats and mice chronically exposed to 72.4 or 67.1 mg MMA/kg/day, respectively. Hemorrhagic, necrotic, ulcerated, or perforated mucosa were also observed in the large intestine of rats exposed to 67.1 mg MMA/kg/day for 2 years. In rats, the damage to the large intestine resulted in intestinal contents leaking into the abdominal cavity and the development of peritonitis. The available data provide suggestive evidence that there may be some species differences in the sensitivity to gastrointestinal damage; however, some of these differences may be due to the route of administration. The lowest adverse effect levels, regardless of duration of exposure, for gastrointestinal effects in rats, mice, rabbits, and dogs are 25.7, 67.1, 12, and 2 mg MMA/kg/day, respectively; the no adverse effect levels in rats and mice (NOAELs were not identified in rabbits and dogs) were 3.0 and 24.9 mg MMA/kg/day. However, the rabbit and dog studies involved bolus administration (gavage and capsule administration), which may have increased sensitivity; the rat and mouse studies involved dietary exposure.

The kidney also appears to be a sensitive target in rats and mice chronically exposed to MMA. An increase in the severity of progressive glomerulonephropathy was observed in female rats exposed to 33.9 mg MMA/kg/day for 2 years and an increase in the incidence of progressive glomerulonephropathy was observed in male mice exposed to 6.0 mg MMA/kg/day for 2 years. Other adverse effects that have been observed in animals exposed to MMA include hypertrophy of the thyroid follicular cells in rats exposed to 33.9 mg MMA/kg/day in the diet for 2 years, reproductive toxicity, and developmental toxicity. Decreases in pregnancy rate and male fertility index were observed in F_0 and F_1 rats exposed to 76 mg MMA/kg/day for 14 weeks prior to mating and during the mating period; the findings were not significantly different than control values but were considered treatment-related because they were outside the range found in historical controls. This study also reported a decrease in pup survival in the F_1 and F_2 offspring of rats exposed to 76 mg MMA/kg/day; as with the reproductive effects, the incidence was not statistically different from controls but was considered biologically significant because survival in the MMA pups was outside the range found in historical controls. Another study reported impaired fetal growth (decreases in fetal weights and incomplete ossification) and minor skeletal defects (an increase in the number of fetuses with supernumerary thoracic ribs and eight lumbar vertebrae) in rat and rabbit fetuses exposed to 500 or 12mg MMA/kg/day, respectively; maternal toxicity was also observed at these dose levels and the effects may be secondary to maternal stress rather than a direct effect on the developing organisms. A 2-year bioassay did not result in significant increases in the incidence of neoplastic lesions in rats and mice exposed to doses as high as 72.4 and 67.1 mg MMA/kg/day, respectively.

DMA. The most sensitive targets of DMA toxicity in rats are the urinary bladder and kidneys. In the bladder, the effects progress from cytotoxicity to cellular necrosis to regenerative proliferation and hyperplasia. At dietary doses of 11 mg DMA/kg/day, cytotoxicity is observed as early as 6 hours after exposure initiation and cellular proliferation (as evident by increased BrdU labeling) was observed after 2 weeks of exposure. After 10 weeks of exposure, necrosis and hyperplasia were also observed. The lowest adverse effect levels for urinary bladder effects following intermediate or chronic duration exposure were 5 mg DMA/kg/day for evidence of regenerative proliferation and 3.1 mg DMA/kg/day for vacuolar degeneration of urothelium and hyperplasia. Vacuolization of the superficial cells of the urothelium was observed in mice exposed to 7.8 mg DMA/kg/day and higher for 2 years. However, unlike the vacuolar degeneration observed in rats, the vacuolization observed in mice was not associated with cytotoxicity, necrosis, inflammation, or hyperplasia.

Kidney damage characterized by increased urinary calcium levels, calcification, nephrocalcinosis, and necrosis of the renal papillae have been observed in rats following intermediate- or chronic-duration exposure. Increases in urine calcium levels and corticomedullary junction calcification were observed in rats exposed to 5 or 10 mg DMA/kg/day for 10 weeks and cortical degeneration and necrosis were observed in rats exposed to 57 mg DMA/kg/day for 4 weeks. Chronic-duration exposure to 3.1 mg DMA/kg/day resulted in an increased incidence of nephrocalcinosis and necrosis of the renal papillae in rats; these lesions are typical in aged rats, although DMA exposure appeared to exacerbate them. An exacerbation of age-related kidney lesion (progressive glomerulonephropathy and nephrocalcinosis) has also been observed in male mice exposed to 37 or 94 mg DMA/kg/day, respectively, for 2 years. A consistent finding in intermediate and chronic rat studies is an increase in urine volume, which corresponds to an increase in water consumption; the toxicological significance of this finding is not known. The observed decreases in electrolyte levels and specific gravity are likely due to the higher urine volume.

Although gastrointestinal effects have been observed in animals exposed to DMA, it does not appear to be as sensitive a target compared to MMA. Diarrhea has been observed in rats exposed to a lethal dose of 190 mg DMA/kg/day for 4 weeks and in dogs administered via 16 mg DMA/kg/day. No gastrointestinal effects were observed in rats or mice chronically exposed to 7.8 or 94 mg DMA/kg/day.

Other adverse effects that have been observed in animals exposed to organic arsenicals include hypertrophy of thyroid follicular cells in rats exposed to 4.0 mg DMA/kg/day in the diet for 13 weeks and 7.8 mg DMA/kg/day in the diet for 2 years and developmental effects in rats and mice. Decreases in fetal growth and delays in ossification have been observed in rat fetuses exposed to ≥36 mg DMA/kg/day; these alterations typically occur at doses associated with decreases in maternal weight gain. Other developmental effects that have been reported include an increase in the incidences of irregular palatine rugae in rats exposed to 30 mg DMA/kg/day, diaphragmatic hernia in rats exposed to 36 mg DMA/kg/day, and cleft palate in mice exposed to 400 mg DMA/kg/day. No developmental effects were observed in rabbits exposed to 12 mg DMA/kg/day.

The available data provide strong evidence that DMA is carcinogenic in rats. A 2-year exposure to DMA resulted in significant increases in the incidence of neoplastic urinary bladder tumors in rats exposed to 7.8 mg DMA/kg/day in the diet or 3.4 mg DMA/kg/day in drinking water. No increases in neoplastic tumors were observed in mice exposed to doses as high as 94 mg DMA/kg/day for 2 years; however, a

50-week exposure to 10.4 mg DMA/kg/day did result in an increased incidence of lung tumors in A/J mice.

The available data for DMA suggest that there are species differences in terms of the critical effects and sensitivity. In rats, the urinary bladder and kidneys are the most sensitive targets with effects occurring at 5 mg DMA/kg/day following intermediate-duration exposure and 3.1 mg DMA/kg/day following chronic-duration exposure. Although the urinary bladder and kidneys are also sensitive targets in mice with LOAELs of 7.8 and 37 mg DMA/kg/day, respectively, following chronic exposure, the effects are not associated with cytotoxicity or elevated urine calcium levels. In dogs, the most sensitive effect is gastrointestinal tract irritation (diarrhea), which occurs at 16 mg DMA/kg/day.

There is concern that the rat may not be a good model to predict the human risk associated with organic arsenic exposure due to the unique toxicokinetic properties of DMA in rats. In humans and most animal species, DMA is rapidly eliminated from the body; >90% of the dose is excreted 2–3 days after dosing. In contrast, DMA is slowly eliminated in rats. One study estimated that 45% of an initial oral DMA dose was eliminated with a half-time of 13 hours; the remaining 55% of the dose DMA dose had an elimination half-time of 50 days. In rats, DMA has a strong affinity for hemoglobin resulting in an accumulation of DMA in erythrocytes. Species differences in DMA metabolism have also been found. In particular, DMA undergoes further methylation to trimethylarsine oxide (TMAO) in rats. In most animal species, almost the entire oral DMA dose is excreted in the urine unchanged; however, in rats, about half of the dose is excreted in the urine as DMA and the other half as TMAO. During the metabolism of DMA to TMAO, DMA(III) is formed as a metabolic intermediate. The formation of this highly reactive intermediate and the excretion of small amounts of DMA(III) in urine may damage the urinary bladder.

There are limited data on the mode of action of DMA for most end points. Recently, there has been considerable research on the mode of action for the development of neoplastic urinary bladder tumors in rats. Although the mechanisms have not been fully elucidated, it has been proposed that the mode of action involves cytotoxicity leading to necrosis and subsequent regeneration of the urinary bladder urothelium. There is strong evidence to suggest that DMA(III) is the causative agent for the urothelial cytotoxicity. The strongest evidence comes from the finding that urinary concentrations of DMA(III) measured in rats exhibiting urothelial cytotoxicity are equivalent to DMA(III) concentrations that are cytotoxic to urothelial cells *in vitro*. Urothelial cytotoxicity, regenerative urothelial proliferation, and urothelial tumors have not been detected in other animal species. Other animal species, including

humans, only metabolize a small percentage of ingested DMA to TMAO; thus, much lower levels of DMA(III) are produced, suggesting that rats may be very sensitive to toxicity of DMA and therefore are not an appropriate model for human risk assessment.

Roxarsone. The available data on the toxicity of roxarsone suggest that following bolus administration, the gastrointestinal tract, kidney, and nervous system are sensitive end points of roxarsone toxicity. Vomiting and gastrointestinal hemorrhage were observed in dogs receiving a single capsulized dose of 50 mg/kg roxarone; no gastrointestinal effects were observed in rats or mice administered 4 or 42 mg/kg/day roxarsone for 2 years. Kidney effects included increases in kidney weight, minimal tubular epithelial cell degeneration, and focal mineralization in rats exposed to 32 mg roxarsone/kg/day for 13 weeks; no kidney effects were observed at 16 mg/kg/day or in mice exposed to doses as high as 136 mg/kg/day for 13 weeks or 43 mg/kg/day for 2 years. Hyperexcitability, ataxia, and/or trembling were observed in rats exposed to 20 mg/kg/day for 13 weeks or 64 mg/kg/day for 13 weeks. A 14-day study in rats reported slight inactivity in rats exposed to 32 mg/kg/day, but this was not observed in longer-term studies. Neurological effects were observed in mice exposed to doses as high as 136 mg/kg/day for 13 weeks or 43 mg/kg/day for 2 years, although a slight decrease in activity at 42 mg/kg/day was reported in a 14 day study. Pigs appear to be especially sensitive to the neurotoxicity of roxarsone. Muscle tremors have been observed at doses of ≥6.3 mg roxarsone/kg/day and myelin degeneration in the spinal cord was noted at 6.3 mg/kg/day. Both the clinical signs of neuropathy and the myelin degeneration followed a time-related pattern. Mild lethargy and ataxia were observed 7 days after exposure initiation, exercise-induced muscle tremors and clonic seizures were observed at day 11, paraparesis was observed at day 22, and paraplegia was observed at day 33. At day 11, equivocal lesions were observed in the cervical spinal cord, and the severity of these lesions increased with time; myelin degeneration was observed in the peripheral nerves and optic nerve starting at day 32 (2 days after exposure termination). Equivocal evidence of carcinogenicity (a slight increase in the incidence of pancreatic tumors) was found in male rats chronically exposed to roxarsone; no increases in neoplastic tumors were observed in female rats or male and female mice.

2.3 MINIMAL RISK LEVELS (MRLs)

Estimates of exposure levels posing minimal risk to humans (MRLs) have been made for arsenic. An MRL is defined as an estimate of daily human exposure to a substance that is likely to be without an appreciable risk of adverse effects (noncarcinogenic) over a specified duration of exposure. MRLs are derived when reliable and sufficient data exist to identify the target organ(s) of effect or the most sensitive

health effect(s) for a specific duration within a given route of exposure. MRLs are based on noncancerous health effects only and do not consider carcinogenic effects. MRLs can be derived for acute, intermediate, and chronic duration exposures for inhalation and oral routes. Appropriate methodology does not exist to develop MRLs for dermal exposure.

Although methods have been established to derive these levels (Barnes and Dourson 1988; EPA 1990i), uncertainties are associated with these techniques. Furthermore, ATSDR acknowledges additional uncertainties inherent in the application of the procedures to derive less than lifetime MRLs. As an example, acute inhalation MRLs may not be protective for health effects that are delayed in development or are acquired following repeated acute insults, such as hypersensitivity reactions, asthma, or chronic bronchitis. As these kinds of health effects data become available and methods to assess levels of significant human exposure improve, these MRLs will be revised.

Inorganic Arsenicals

Inhalation MRLs. No inhalation MRLs were derived for inorganic arsenic. Human data suggest that dermal or respiratory effects may be the most prevalent (Lagerkvist et al. 1986; Mohamed 1998; Perry et al. 1948); respiratory or immunological effects appeared to be the most common following inhalation exposure to inorganic arsenic in animals (Aranyi et al. 1985; Holson et al. 1999). Adequate human studies evaluating dose-response relationships for noncancer end points were not located for inorganic arsenic, and animal data on the health effects of inorganic arsenic following inhalation exposure are limited to studies that did not evaluate a suitable range of health effects. Lacking suitable studies upon which to base the MRLs, no inhalation MRLs were derived for inorganic arsenic.

Oral MRLs

- An MRL of 0.005 mg As/kg/day has been derived for acute-duration (14 days or less) oral exposure to inorganic arsenic.

Mizuta et al. (1956) summarized findings from 220 poisoning cases associated with an episode of arsenic contamination of soy sauce in Japan. The soy sauce was contaminated with approximately 0.1 mg As/mL, probably as calcium arsenate. Arsenic intake in the cases was estimated by the researchers to be 3 mg/day (0.05 mg/kg/day, assuming 55 kg average body weight for this Asian population). The duration of exposure was 2–3 weeks in most cases. The primary symptoms were edema of the face, and gastrointestinal and upper respiratory symptoms initially, followed by skin lesions and neuropathy in

some patients. Other effects included mild anemia and leukopenia, mild degenerative liver lesions and hepatic dysfunction, abnormal electrocardiogram, and ocular lesions. For derivation of the acute oral MRL, facial edema and gastrointestinal symptoms (nausea, vomiting, diarrhea), which were characteristic of the initial poisoning and then subsided, were considered to be the critical effects. The MRL of 0.005 mg As/kg/day was calculated by applying an uncertainty factor of 10 (10 for use of a lowest-observed-adverse-effect level (LOAEL) and 1 for human variability) to the LOAEL of 0.05 mg As/kg/day (see Appendix A for MRL worksheets).

An intermediate-duration oral MRL for inorganic arsenic was not derived due to inadequacy of the database. The lowest LOAEL identified in a limited number of intermediate-duration human studies available was 0.05 mg As/kg/day in a study by Mizuta et al. (1956) (summarized above). While this study was considered appropriate to derive an acute-duration oral MRL for inorganic arsenic, there is considerable uncertainty regarding what the effects and severity might be beyond the relatively short 2–3 weeks of exposure that most subjects experienced. There are numerous studies in animals dosed for intermediate durations, but as indicated in Section 3.5.3, animals are not appropriate models for effects of inorganic arsenic in humans.

- An MRL of 0.0003 mg As/kg/day has been derived for chronic-duration (365 days or more) oral exposure to inorganic arsenic.

Tseng et al. (1968) and Tseng (1977) investigated the incidence of Blackfoot Disease and dermal lesions (hyperkeratosis and hyperpigmentation) in a large number of poor farmers (both male and female) exposed to high levels of arsenic in well water in Taiwan. A control group consisting of 17,000 people, including one group in which arsenic exposure was "undetermined" and which included those villages where arsenic-contaminated wells were no longer used or the level could not be classified, and a control population of 7,500 people who consumed water from wells almost free of arsenic (0.001–0.017 ppm) was also examined. The authors stated that the incidence of dermal lesions increased with dose, but individual doses were not provided. However, incidence data were provided based on stratification of the exposed population into low (<300 µg/L), medium (300–600 µg/L), or high (>600 µg/L) exposure levels. Doses were calculated from group mean arsenic concentrations in well water, assuming the intake parameters described by IRIS (IRIS 2007). Accordingly, the control, low-, medium-, and high-exposure levels correspond to doses of 0.0008, 0.014, 0.038, and 0.065 mg As/kg/day, respectively. The no-observed-adverse-effect level (NOAEL) identified by Tseng (1977) (0.0008 mg As/kg/day) was limited by the fact that the majority of the population was <20 years of age and the incidence of skin lesions increased as a function of age, and because the estimates of water intake and dietary arsenic intake are

highly uncertain. Schoof et al. (1998) estimated that dietary intakes of arsenic from rice and yams may have been 15–211 µg/day (mean=61 µg/day), based on arsenic analyses of foods collected in Taiwan in 1993–1995. Use of the 50 µg/day estimate would result in an approximate doubling of the NOAEL (0.0016 mg/kg/day) (see Appendix A for MRL worksheets). The MRL was derived by applying an uncertainty factor of 3 (for human variability) to the NOAEL of 0.0008 mg/kg/day.

The MRL is supported by a large number of well-conducted epidemiological studies that identify reliable NOAELs and LOAELs for dermal effects. EPA (1981b) identified a NOAEL of 0.006–0.007 mg As/kg/day for dermal lesions in several small populations in Utah. Harrington et al. (1978) identified a NOAEL of 0.003 mg As/kg/day for dermal effects in a small population in Alaska. Guha Mazumder et al. (1988) identified a NOAEL of 0.009 mg As/kg/day and a LOAEL of 0.006 mg As/kg/day for pigmentation changes and hyperkeratosis in a small population in India. Haque et al. (2003) identified a LOAEL of 0.002 mg As/kg/day for hyperpigmentation and hyperkeratosis in a case-control study in India. Cebrián et al. (1983) identified a NOAEL of 0.0004 mg As/kg/day and a LOAEL of 0.022 mg As/kg/day in two regions in Mexico. Borgoño and Greiber (1972) and Zaldívar (1974) identified a LOAEL of 0.02 mg As/kg/day for abnormal skin pigmentation in patients in Chile, and Borgoño et al. (1980) identified a LOAEL of 0.01 mg As/kg/day for the same effect in school children in Chile. Valentine et al. (1985) reported a NOAEL of 0.02 mg As/kg/day for dermal effects in several small populations in California. Collectively, these studies indicate that the threshold dose for hyperpigmentation and hyperkeratosis is approximately 0.002 mg As/kg/day. While many of these studies also identified effects on other end points at these exposure levels, including effects on gastrointestinal (Borgoño and Greiber 1972; Cebrián et al. 1983; Guha Mazumder et al. 1988; Zaldívar 1974), cardiovascular (Tseng et al. 1995, 1996), hepatic (Hernández-Zavala et al. 1998), and neurological end points (Guha Mazumder et al. 1988; Lianfang and Jianzhong 1994; Tsai et al. 2003), the overall database for dermal effects is considerably stronger than for effects on other end points.

Organic Arsenicals

Inhalation MRLs. No inhalation MRLs were derived for organic arsenic. Human data are limited to an occupational exposure study of workers exposed to 0.065 mg/m^3 ansanilic acid (Watrous and McCaughey 1945). The exposed workers more frequently complained of keratosis than nonexposed workers. A limited number of animal studies have examined the toxicity of organic arsenicals following inhalation exposure. Respiratory distress and diarrhea were observed in rats and mice exposed to high concentrations of MMA and DMA (Stevens et al. 1979); at lower concentrations (1,540–3,150 mg DMA/m^3), respiratory irritation, as evidenced by a decrease in respiration rate, was observed in animals

exposed to MMA or DMA (Stevens et al. 1979). The acute-duration studies do not clearly identify the most sensitive targets of inorganic arsenical toxicity; the available studies are of limited scope and none included a comprehensive histological examination.

One study examined the toxicity of DMA in rats following intermediate-duration exposure. This study (Whitman 1994) found an increase in intracytoplasmic eosinophilic globules in the nasal turbinates of rats exposed to 34 or 100 mg/m^3 DMA 6 hours/day, 5 days/week for 67–68 exposures; no other adverse effects were observed in this comprehensive study. As discussed in greater detail in the oral MRL section, the toxicokinetic properties of DMA in rats differ from other species and rats do not appear to be a good model for human exposure. The half-time of DMA in the body is much longer in rats compared to other species, including humans, and DMA is more extensively methylated in rats. In the absence of data to determine whether the observed effect is due to a direct interaction of DMA, derivation of an intermediate-duration MRL using rat data is not recommended at this time.

No studies examined the chronic toxicity of organic arsenicals precluding the derivation of a chronic-duration inhalation MRL.

Oral MRLs

MMA. A limited number of animal studies have examined the acute oral toxicity of MMA. These studies consisted of LD_{50} studies in rats (Gur and Nyska 1990), mice (Kaise et al. 1989), and rabbits (Jaghabir et al. 1988) and developmental toxicity studies in rats (Irvine et al. 2006) and rabbits (Irvine et al. 2006); all studies administered MMA via gavage. Adverse effects reported in the LD_{50} studies included diarrhea in rats at 2,030 mg monosodium methane arsonate (MSMA)/kg (Gur and Nyska 1990), mice at 2,200 mg MMA/kg (Kaise et al. 1989) and rabbits at 60 mg MSMA/kg (Jaghabir et al. 1988) and respiratory arrest in mice at 1,800 mg MMA/kg/day (Kaise et al. 1989). These doses were at or near the LD_{50} levels of 2,449 mg MSMA/kg, 1,800 mg MMA/kg, 100 mg MSMA/kg for the rats, mice, and rabbits, respectively. In the developmental toxicity studies (Irvine et al. 2006), maternal effects included decreases in maternal body weight gain in rats (17% less than controls) and rabbits (70% less than controls) receiving gavage doses of 100 and 12 mg MMA/kg/day, respectively, and loose feces/diarrhea in rabbit does administered 12 mg MMA/kg/day. The NOAELs for maternal effects were 10 and 7 mg MMA/kg/day in the rats and rabbits, respectively. Minor developmental effects (decreased fetal weight, incomplete ossification, and supernumerary ribs) were also observed at the maternally toxic doses in the rats and rabbits (Irvine et al. 2006); these effects were probably secondary to the maternal stress. These

data, coupled with the results of longer-term studies (Arnold et al. 2003; Waner and Nyska 1988), suggest that the gastrointestinal tract is a sensitive target of MMA toxicity. The rabbit developmental toxicity study (Irvine et al. 2006) identified the lowest LOAEL (12 mg MMA/kg/day) for gastrointestinal irritation. However, this study is not suitable for the derivation of an acute-duration oral MRL for MMA because the MMA was administered via bolus doses. It is likely that the observed gastrointestinal effect is a concentration-dependent effect; thus, at a given dose level, effects are more likely to occur following bolus administration. A marked decrease in body weight gain was also observed at this dose level.

- An MRL of 0.1 mg MMA/kg/day has been derived for intermediate-duration (15–364 days) oral exposure to MMA.

Three studies have examined the intermediate-duration toxicity of MMA; two of these are chronic-duration studies reporting diarrhea and decreases in body weight gain after MMA exposure for <1 year. Diarrhea was observed in rats exposed to 30.2 mg MMA/kg/day in the diet (Arnold et al. 2003) and in dogs exposed via a capsule to 2 mg MMA/kg/day (Waner and Nyska 1988). Decreases in body weight were observed at the next highest doses, 106.9 mg MMA/kg/day in rats and 8 mg MMA/kg/day in dogs. In the rat study (Arnold et al. 2003), diarrhea was observed in 16.7 and 40% of the males and females, respectively, exposed to 30.2/35.9 mg MMA/kg/day during the first 52 weeks of the study; diarrhea first occurred after 4 weeks of exposure. At the highest dose level (106.9 mg MMA/kg/day), diarrhea was observed in all exposed male and female rats. In dogs, the increased incidence of diarrhea first occurred during weeks 25–28; at the highest dose tested in the study (35 mg MMA/kg/day), vomiting was also observed. A NOAEL of 3.5 mg MMA/kg/day was identified in the rat study; a NOAEL was not identified in the dog study. The remaining study in the intermediate-duration database is a 2-generation study that reported reproductive (decreased pregnancy rate and male fertility index in F_0 and F_1 generations) and developmental (decreased pup survival in F_1 and F_2 generation) effects in rats exposed to 76 mg MMA/kg/day in the diet (Schroeder 1994). The lowest LOAEL identified in the intermediate-duration database is 2 mg MMA/kg/day for diarrhea in dogs (Waner and Nyska 1988). Although dogs appear to be more sensitive to the gastrointestinal effects of MMA, a direct comparison of the two studies is not possible due to the difference in the routes of exposure. It is possible that the bolus administration of MMA, in the form of a capsule, resulted in increased sensitivity of the dogs. Because the most likely route of exposure for humans would be ingestion and the critical effect appears to be irritation of the gastrointestinal tract, studies involving bolus administration (gavage or capsule) were not considered for derivation of oral MRLs. The Arnold et al. (2003) and Schroeder (1994) studies were considered as the basis for an intermediate-duration MRL. Of these two studies, Arnold et al. (2003) identified the lowest

LOAEL, 30.2 mg MMA/kg/day, for gastrointestinal effects and was selected as the principal study for the intermediate-duration oral MRL.

Arnold et al. (2003) exposed groups of 60 male and 60 female Fischer 344 rats to 0, 50, 400, or 1,300 ppm MMA in the diet for 104 weeks. Using the average doses for weeks 1–50 reported in an unpublished version of this study (Crown et al. 1990), doses of 0, 3.5, 30.2, and 106.9 mg MMA/kg/day and 0, 4.2, 35.9, and 123.3 mg MMA/kg/day were calculated for males and females, respectively. Body weights, food consumption, and water intake were monitored regularly. Blood was taken at 3, 6, and 12 months for clinical chemistry measurements, and urine samples were collected at the same interval. Mortality was increased in high-dose males and females during the first 52 weeks of the study. Body weights were decreased in the mid- and high-dose groups of both sexes; however, at 51 weeks, only the body weight for the high-dose males was <10% of the control weight (14.5%). Food and water consumption was increased in the mid- and high-dose groups. Diarrhea was observed in 100% of the high-dose males and females and in 16.7 and 40% of the mid-dose males and females during the first 52 weeks of exposure. Diarrhea first occurred after 3 weeks of exposure to the high dose and 4 weeks of exposure to the mid-dose group; the severity of the diarrhea was dose-related. The gastrointestinal system was the primary target in animals dying early; numerous macroscopic and histological alterations were observed.

A benchmark dose (BMD) analysis of the incidence data for diarrhea was conducted; details of this analysis are presented in Appendix A. Using the female incidence data, a BMD (BMD_{10}) of 16.17 mg MMA/kg/day, which corresponds to a 10% increase in the incidence of diarrhea, was calculated; the 95% lower confidence limit on the BMD ($BMDL_{10}$) was 12.38 mg MMA/kg/day. The female incidence data were selected over the male data because the females may be more sensitive than the males. Thus, the intermediate-duration oral MRL of 0.1 mg MMA/kg/day is based on the $BMDL_{10}$ of 12.38 mg MMA/kg/day in female rats and an uncertainty factor of 100 (10 to account for animal to human extrapolation and 10 for human variability).

- An MRL of 0.01 mg MMA/kg/day has been derived for chronic-duration (365 days or longer) oral exposure to MMA.

The available data on the chronic toxicity of MMA in animals (no human data are available) suggest that the gastrointestinal tract and the kidney are the most sensitive targets. Diarrhea has been observed in rats and mice exposed to MMA in the diet for 2 years (Arnold et al. 2003). The NOAEL and LOAEL values for diarrhea are 3.0 and 25.7 mg MMA/kg/day in rats, respectively, and 24.9 and 67.1 mg MMA/kg/day

in mice, respectively. At 72.4 mg MMA/kg/day, necrotic, ulcerated, or perforated mucosa and metaplasia were observed in the cecum, colon, and rectum of rats. Squamous metaplasia was also observed in the cecum, colon, and rectum of mice exposed to 67.1 mg MMA/kg/day. Diarrhea was observed in dogs exposed via capsule to 2 mg MMA/kg/day for 52 weeks (Waner and Nyska 1988). The bolus administration used in the dog study probably increased the dog's sensitivity to MMA. In both the rats and mice, chronic administration of MMA resulted in an exacerbation of chronic progressive nephropathy. In female rats, significant increases in the severity of chronic progressive nephropathy were observed at 33.9 and 98.5 mg MMA/kg/day; the NOAEL was 3.9 mg MMA/kg/day (Arnold et al. 2003). In male mice, there was an increased incidence of slight progressive nephropathy at doses ≥6.0 mg MMA/kg/day; the NOAEL was 1.2 mg MMA/kg/day (Arnold et al. 2003; incidence data reported in Gur et al. 1991). Nephrocalcinosis was also observed in male mice exposed to ≥24.9 mg MMA/kg/day (Arnold et al. 2003). Other effects that have been observed following chronic exposure MMA include decreased weight gain in male and female rats exposed to 25.7/33.9 mg MMA/kg/day and higher (Arnold et al. 2003) and hypertrophy of the thyroid follicular epithelium in female rats exposed to ≥33.9 mg MMA/kg/day (Arnold et al. 2003). A variety of other lesions including peritonitis, pancreatitis, inflammation of the ureter, uterus, prostate, testes, epididymis, and seminal vesicles, hydronephrosis, pyelonephritis, and cortical tubular cystic dilation were also observed in rats; however, these alterations were probably secondary to the ulceration and perforation of the large intestine, which resulted in leaking of gastrointestinal contents into the abdominal cavity. Hyperplasia of the urinary bladder was also observed in rats exposed to 2.1 mg MMA/kg/day as MMA in drinking water for 2 years (Shen et al. 2003). Although hyperplasia of the urinary bladder is commonly observed in rats exposed to DMA, it was not observed in the Arnold et al. (2003) study at doses as high as 72.4 mg MMA/kg/day; thus, the significance of the results of the Shen et al. (2003) study is not known.

The lowest reliable LOAEL identified in the chronic oral MMA database was 6.0 mg MMA/kg/day for an increased incidence of progressive glomerulonephropathy in mice (Arnold et al. 2003). Although the investigators noted that the kidney lesions were consistent with the normal spectrum of spontaneous renal lesions and that there was no difference in character or severity of lesions between groups, ATSDR considers the dose-related increase in glomerulonephropathy to be treatment-related.

In the Arnold et al. (2003) study (incidence data reported in Gur et al. 1991), groups of 52 male and 52 female $B6C3F_1$ mice were exposed to 0, 10, 50, 200, or 400 ppm of MMA in the diet for 104 weeks. The average doses reported in Gur et al. (1991) were 0, 1.2, 6.0, 24.9, and 67.1 mg MMA/kg/day for males and 0, 1.4, 7.0, 31.2, and 101 mg MMA/kg/day for females. Body weights, food consumption, and

water intake were monitored regularly. Blood was taken at 3, 6, 12, 18, and 24 months for white cell counts. At sacrifice, complete necropsies were performed, including histological examination of at least 13 organs. No treatment-related increases in mortality were observed. Significant decreases in body weights were observed in males and females exposed to 67.1 or 101 mg MMA/kg/day, respectively; at week 104, the males and females weighed 17 and 23%, respectively, less than controls. Food consumption was increased in females exposed to 101 mg MMA/kg/day, and water consumption was increased in 67.1 mg MMA/kg/day males and 31.2 and 101 mg MMA/kg/day females. Loose and mucoid feces were noted in mice exposed to 67.1/101 mg MMA/kg/day. No changes were seen in white cell counts of either sex. Small decreases in the weights of heart, spleen, kidney, and liver weights were observed in some animals, but the decreases were not statistically significant. Squamous metaplasia of the cecum, colon, and rectum was observed at 67.1/101 mg MMA/kg/day. The incidence of metaplasia in the cecum, colon, and rectum were 29/49, 14/49, and 39/49 in males and 38/52, 17/52, and 42/52 in females; metaplasia was not observed in other groups of male or female mice. An increased incidence of progressive glomerulonephropathy (incidence of 25/52, 27/52, 38/52, 39/52, and 46/52 in the 0, 1.2, 6.0, 24.9, and 67.1 mg MMA/kg/day males, respectively) was observed in males; the incidence was significantly higher (Fisher Exact Test) than controls at ≥6.0 mg MMA/kg/day. Significant increases in the incidence of nephrocalcinosis was observed in the males at 24.9 and 67.1 mg MMA/kg/day (Fisher Exact Test) (incidences of 25/52, 30/52, 30/52, 45/52, and 45/51 in males and 0/52, 1/52, 1/52, 2/52, and 5/52 in females). A reduction in the incidence of cortical focal hyperplasia in the adrenal gland of male mice exposed to 67.1 mg MMA/kg/day was possibly related to MMA exposure; the toxicological significance of this effect is not known. Thus, this study identifies a NOAEL of 1.2 mg MMA/kg/day and a LOAEL of 6.0 mg MMA/kg/day for progressive glomerulonephropathy in male mice.

As described in greater detail in Appendix A, BMD was applied to the incidence data for progressive glomerulonephropathy in male mice using all available dichotomous models in EPA's Benchmark Dose Software (version 1.4.1) to calculate predicted doses associated with a 10% extra risk. As assessed by the Akaike's Information Criteria (AIC), the log-logistic model provided the best fit to the data. The predicted BMD_{10} and $BMDL_{10}$ are 2.09 and 1.09 mg MMA/kg/day. The $BMDL_{10}$ was selected as the point of departure and divided by an uncertainty factor of 100 (10 for extrapolation from animals to humans and 10 for human variability) to derive a chronic-duration oral MRL of 0.01 mg MMA/kg/day.

DMA. As discussed in greater detail in Section 2.2, urinary bladder effects characterized by cytotoxicity and regenerative proliferation and hyperplase have been observed in rats, but not in other species. The LOAELs for these effects are lower than the LOAELs for sensitive effects in other species. Additionally,

rats have a much greater capacity than other species to metabolize ingested DMA to form DMA(III) (a reactive intermediate) and TMAO (Cohen et al. 2006; Marafante et al. 1987b; Yoshida et al. 1998). It is likely that DMA(III) is the causative agent for the urothelial cytoxicity observed in rats (Cohen et al. 2006). Thus, rats were not considered a suitable model for humans and these data were not considered for derivation of MRLs for DMA.

There are limited data to assess the acute toxicity of DMA in species other than rats. Diarrhea, increased startle reflex, and ataxia were observed in mice exposed to a lethal gavage dose of 1,757 mg DMA/kg (Kaise et al. 1989); vomiting and diarrhea were also observed during the second week of a 52-week study in dogs exposed via capsule to 16 mg DMA/kg/day (Zomber et al. 1989). The remaining studies in the acute database are developmental toxicity studies in mice and rabbits. Rabbits appear to be more sensitive than mice to maternal and developmental effects. Gavage exposure to 48 mg DMA/kg/day on gestational days 7–19 resulted in maternal weight loss and abortion in approximately 75% of the does; no adverse effects were observed at 12 mg DMA/kg/day (Irvine et al. 2006). In mice, decreases in maternal body weight gain were observed at gavage doses of 200 mg DMA/kg/day on gestational days 7–16 (Rogers et al. 1981), decreases in fetal body weight, delays in ossification, and increased incidence of cleft palate were observed at 400 mg DMA/kg/day on gestational days 7–16 (Rogers et al. 1981) and fetal deaths, decreases in growth, and increased incidence of malformations were observed in mice administered 1,600 mg DMA/kg on gestational day 8 (Kavlock et al. 1985). The acute-duration database for DMA was not considered adequate for derivation of an oral MRL. The database is lacking a comprehensive toxicity study, which would be useful in establishing the critical target of toxicity. In a chronic-duration study in mice (Arnold et al. 2006), vacuolization was observed in the urinary bladder at ≥7.8 mg DMA/kg/day; it is not known if these effects would also be observed after acute-duration exposure. Thus, it is not known if systemic effects would occur at lower doses than the maternal developmental effects observed in rabbits exposed to 48 mg DMA/kg/day (Irvine et al. 2006); an acute-duration oral MRL for DMA is not recommended at this time.

Excluding rat studies, the database on the toxicity of DMA following intermediate-duration oral exposure is limited to a chronic study of dogs exposed to DMA via capsule 6 days/week for 52 weeks (Zomber et al. 1989). Diarrhea and vomiting were observed at 16 and 40 mg DMA/kg/day starting after the first week of exposure. A slight decrease in erythrocyte levels and increase in total leukocyte levels were observed in males exposed to 40 mg DMA/kg/day for 51 weeks. This dog study was not selected as the basis of an MRL because it is likely that bolus administration of DMA would increase sensitivity to the gastrointestinal effects.

- An MRL of 0.02 mg DMA/kg/day has been derived for chronic-duration (365 days or longer) oral exposure to DMA.

Two studies investigated the chronic-duration toxicity of DMA in a species other than rats. In dogs, diarrhea and vomiting were observed after 52 weeks of exposure to 16 or 40 mg As/kg/day (Zomber et al. 1989); no histological alterations were observed. In mice exposed to DMA in the diet for 2 years, vacuolization of the urothelium in the urinary bladder was observed at ≥7.8 mg DMA/kg/day and progressive glomerulonephropathy was observed at ≥37 mg DMA/kg/day (Arnold et al. 2006). As noted in Section 2.2, the vacuolization was not associated with cytotoxicity or proliferation. Because the bladder effects in mice occurred at the lowest adverse effect level for the database, it was selected as the critical effect and Arnold et al. (2006) was selected as the principal study.

In the Arnold et al. (2006) study, groups of 56 male and 56 female $B6C3F_1$ mice were exposed to 0, 8, 40, 200, or 500 ppm DMA in the diet for 2 years; the results of this study were also reported in an unpublished paper (Gur et al. 1989b) submitted to EPA under Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA). The investigators reported dietary doses of approximately 0, 1.3, 7.8, 37, and 94 mg DMA/kg/day. The following parameters were used to assess toxicity: clinical observations, body weight, food consumption, water consumption, differential leukocyte levels measured at 12, 18, and 24 months in mice in the control and 94 mg DMA/kg/day groups, organ weights (brain, kidneys, liver, and testes), and histopathological examination of major tissues and organs. No deaths or treatment-related clinical signs were observed. Decreases in body weight gain were observed in the male mice exposed to 94 mg DMA/kg/day; the difference was <10% and not considered adverse. An increase in water consumption was observed in males exposed to 94 mg DMA/kg/day during weeks 60–96. In the female mice exposed to 51 mg As/kg/day, a statistically significant decrease in lymphocytes and an increase in monocytes were observed at 24 months. Treatment related nonneoplastic alterations were observed in the urinary bladder and kidneys. In the urinary bladder, increases in the vacuolization of the superficial cells of the urothelium were observed in males exposed to 37 or 94 mg DMA/kg/day (0/44, 1/50, 0/50, 36/45, 48/48) and in females exposed to 7.8, 37, and 94 mg DMA/kg/day (1/45, 1/48, 26/43, 47/47, 43/43); incidence data reported in Gur et al. (1989b). An increased incidence of progressive glomerulonephropathy was observed in males at 37 mg DMA/kg/day (16/44, 22/50, 17/50, 34/45, 30/50) and an increased incidence of nephrocalcinosis was also observed in male mice at 94 mg DMA/kg/day (30/44, 25/50, 27/50, 29/50, 45/50). Neoplastic alterations were limited to an increased incidence of fibrosarcoma of the skin in females exposed to 94 mg DMA/kg/day (the incidence of 3/56, 0/55, 1/56,

1/56, and 6/56 in the 0, 1.3, 7.8, 37, and 94 mg DMA/kg/day groups, respectively); however, it was concluded that this lesion was not related to DMA exposure.

As described in detail in Appendix A, BMD analysis was applied to the incidence data for vacuolization of the urothelium in the urinary bladder of female mice using all available dichotomous models in EPA's Benchmark Dose Software (version 1.4.1) to calculate predicted doses associated with a 10% extra risk. As assessed by the AIC, the multi-stage model provided the best fit to the data. The predicted BMD_{10} and $BMDL_{10}$ are 2.68 and 1.80 mg DMA/kg/day. The $BMDL_{10}$ was selected as the point of departure and divided by an uncertainty factor of 100 (10 for extrapolation from animals to humans and 10 for human variability) to derive a chronic-duration oral MRL of 0.02 mg DMA/kg/day.

Roxarsone. A series of three National Toxicology Program (NTP) studies in rats and mice (NTP 1989b) and a study in dogs (Kerr et al. 1963) have examined the acute toxicity of roxarsone; adverse effects have also been reported within the first 2 weeks of a longer-term study in pigs (Rice et al. 1985; Kennedy et al. 1986). A single exposure study reported diarrhea and ataxia in rats and mice exposed to doses that exceeded the LD_{50} (NTP 1989b). In another study, no alterations in hematological parameters (only end point assessed) were found after 10 or 9 days of dietary exposure in rats and mice, respectively (NTP 1989b). In a 14-day study (NTP 1989b), a decrease in body weight gain and slight inactivity were observed in rats exposed to 32 mg roxarsone/kg/day and slight inactivity was observed in mice exposed to 42 mg roxarsone/kg/day; a decrease in body weight gain was also observed in mice exposed to 168 mg roxarsone/kg/day. The dog study was considered inadequate because a small number (n=3) of animals were tested and no control group was used. In a 30-day dietary exposure study in pigs (Rice et al. 1985; Kennedy et al. 1986), mild lethargy and ataxia were observed from day 7 forward and exercise-induced muscle tremors and clonic seizures were observed from day 11 forward in pigs exposed to 6.3 mg roxarsone/kg/day; equivocal evidence of myelin degeneration was also observed in pigs sacrificed after 11 days of exposure. These data clearly identify pigs as the most sensitive species following acute-duration oral exposure; in the absence of data to the contrary, it is assumed that pigs are a good model to predict the toxic potential of roxarsone in humans. Because the lowest dose tested in pigs was a serious LOAEL for neurotoxicity and a NOAEL for this effect was not identified, an acute-duration oral MRL cannot be derived for roxarsone.

As with the acute-duration database, pigs appear to be the most sensitive species; neurotoxicity has been observed at ≥6.3 mg roxarsone/kg/day. In a study reported by Rice et al. (1985) and Kennedy et al. (1986), exercise-induced muscle tremors and clonic convulsions were observed in pigs during the early

part of the study; when the pigs returned to a recumbent position, the seizures and tremors stopped. Paraparesis, evidenced by reluctance to rise and the pigs dragging their hindquarters on the ground, was observed at day 22; paraplegia was observed 2 days after exposure termination. In addition to these clinical signs of neuropathy, histological alterations consisting of myelin degeneration was observed in the spinal cord, peripheral nerves, and optic nerve. The lesions were first detected in the spinal cord on day 15 and in the peripheral nerves and optic nerve 2 days after exposure termination. The Rice et al. (1985) and Kennedy et al. (1986) studies did not identify a NOAEL. Muscle tremors were also observed in pigs exposed to 10 mg roxarsone/kg/day for 28 days (Edmonds and Baker 1986). This study was not designed to assess neurotoxicity and did not include histological examination of the spinal cord or nerves. Trembling, ataxia, and hyperexcitability were also observed in rats exposed to 64 mg roxarsone/kg/day for 13 weeks (NTP 1989b). Other effects that have been observed include tubular degeneration and focal regenerative hyperplasia in the kidney and decreased body weight in rats exposed to 32 mg roxarsone/kg/day for 13 weeks (NTP 1989b) and decreased body weight in mice at 136 mg roxarsone/kg/day for 13 weeks (NTP 1989b). The lowest identified adverse effect level is 6.3 mg roxarsone/kg/day for serious neurological effects in pigs (Kennedy et al. 1986; Rice et al. 1985) and is not suitable for the derivation of an intermediate-duration oral MRL.

The chronic toxicity of roxarsone has been examined in rats (NTP 1989b; Prier et al. 1963), mice (NTP 1989b; Prier et al. 1963), and dogs (Prier et al. 1963) in 2-year dietary exposure studies. None of these studies reported adverse effects at the highest doses tested; the highest NOAELs for each species are 10, 43, and 5 mg roxarsone/kg/day for rats, mice, and dogs, respectively. The results from shorter duration studies suggest that pigs are more sensitive to the neurotoxic effects of roxarsone than rats, mice, or dogs. Because no chronic duration pig studies were identified and deriving an MRL using a potentially less sensitive species may not be protective of human health, a chronic-duration oral MRL is not recommended at this time.

3. HEALTH EFFECTS

3.1 INTRODUCTION

The primary purpose of this chapter is to provide public health officials, physicians, toxicologists, and other interested individuals and groups with an overall perspective on the toxicology of arsenic. It contains descriptions and evaluations of toxicological studies and epidemiological investigations and provides conclusions, where possible, on the relevance of toxicity and toxicokinetic data to public health.

A glossary and list of acronyms, abbreviations, and symbols can be found at the end of this profile.

3.2 DISCUSSION OF HEALTH EFFECTS BY ROUTE OF EXPOSURE

To help public health professionals and others address the needs of persons living or working near hazardous waste sites, the information in this section is organized first by route of exposure (inhalation, oral, and dermal) and then by health effect (death, systemic, immunological, neurological, reproductive, developmental, genotoxic, and carcinogenic effects). These data are discussed in terms of three exposure periods: acute (14 days or less), intermediate (15–364 days), and chronic (365 days or more).

Levels of significant exposure for each route and duration are presented in tables and illustrated in figures. The points in the figures showing no-observed-adverse-effect levels (NOAELs) or lowest-observed-adverse-effect levels (LOAELs) reflect the actual doses (levels of exposure) used in the studies. LOAELs have been classified into "less serious" or "serious" effects. "Serious" effects are those that evoke failure in a biological system and can lead to morbidity or mortality (e.g., acute respiratory distress or death). "Less serious" effects are those that are not expected to cause significant dysfunction or death, or those whose significance to the organism is not entirely clear. ATSDR acknowledges that a considerable amount of judgment may be required in establishing whether an end point should be classified as a NOAEL, "less serious" LOAEL, or "serious" LOAEL, and that in some cases, there will be insufficient data to decide whether the effect is indicative of significant dysfunction. However, the Agency has established guidelines and policies that are used to classify these end points. ATSDR believes that there is sufficient merit in this approach to warrant an attempt at distinguishing between "less serious" and "serious" effects. The distinction between "less serious" effects and "serious" effects is considered to be important because it helps the users of the profiles to identify levels of exposure at which major health effects start to appear. LOAELs or NOAELs should also help in determining whether or not

the effects vary with dose and/or duration, and place into perspective the possible significance of these effects to human health.

The significance of the exposure levels shown in the Levels of Significant Exposure (LSE) tables and figures may differ depending on the user's perspective. Public health officials and others concerned with appropriate actions to take at hazardous waste sites may want information on levels of exposure associated with more subtle effects in humans or animals (LOAELs) or exposure levels below which no adverse effects (NOAELs) have been observed. Estimates of levels posing minimal risk to humans (Minimal Risk Levels or MRLs) may be of interest to health professionals and citizens alike.

Levels of exposure associated with carcinogenic effects (Cancer Effect Levels, CELs) of arsenic are indicated in Tables 3-1 and 3-3 and Figures 3-1 and 3-3. Because cancer effects could occur at lower exposure levels, Figures 3-1 and 3-3 also show a range for the upper bound of estimated excess risks, ranging from a risk of 1 in 10,000 to 1 in 10,000,000 (10^{-4} to 10^{-7}), as developed by EPA.

A User's Guide has been provided at the end of this profile (see Appendix B). This guide should aid in the interpretation of the tables and figures for Levels of Significant Exposure and the MRLs.

Chemical Forms of Concern. Analysis of the toxic effects of arsenic is complicated by the fact that arsenic can exist in several different oxidation states and many different inorganic and organic compounds. Most cases of human toxicity from arsenic have been associated with exposure to inorganic arsenic, so these compounds are the main focus of this profile.

The most common inorganic arsenical in air is arsenic trioxide (As_2O_3), while a variety of inorganic arsenates (AsO_4^{-3}) or arsenites (AsO_2^-) occur in water, soil, or food. A number of studies have noted differences in the relative toxicity of these compounds, with trivalent arsenites tending to be somewhat more toxic than pentavalent arsenates (Byron et al. 1967; Gaines 1960; Maitani et al. 1987a; Sardana et al. 1981; Willhite 1981). However, these distinctions have not been emphasized in this profile, for several reasons: (1) in most cases, the differences in the relative potency are reasonably small (about 2–3-fold), often within the bounds of uncertainty regarding NOAEL or LOAEL levels; (2) different forms of arsenic may be interconverted, both in the environment (see Section 6.3) and the body (see Section 3.4); and (3) in many cases of human exposure (especially those involving intake from water or soil, which are of greatest concern to residents near wastes sites), the precise chemical speciation is not known.

Gallium arsenide (GaAs) is another inorganic arsenic compound of potential human health concern, due to its widespread use in the microelectronics industry. Available toxicokinetic data suggest that although gallium arsenide is poorly soluble, it undergoes slow dissolution and oxidation to form gallium trioxide and arsenite (Webb et al. 1984, 1986). Therefore, the toxic effects of this compound are expected to be attributable to the arsenite that is liberated, plus the additional effects of the gallium species.

It is beyond the scope of this profile to provide detailed toxicity data on other less common inorganic arsenic compounds (e.g., As_2S_3), but these are expected to be of approximately equal or lesser toxicity than the oxycompounds, depending mainly on solubility (see Section 3.4).

Although organic arsenicals are usually viewed as being less toxic than the inorganics, several methyl and phenyl derivatives of arsenic that are widely used in agriculture are of possible human health concerns based on their toxicity in animal species (Arnold et al. 2003, 2006; NTP 1989b). Chief among these are monomethylarsonic acid (MMA) and its salts (monosodium methane arsonate [MSMA] and disodium methane arsonate [DSMA]), dimethylarsinic acid (DMA, also known as cacodylic acid) and its sodium salt (sodium dimethyl arsinite, or sodium cacodylate), and roxarsone (3-nitro-4-hydroxyphenylarsonic acid). However, it should be noted that food is the largest contributor to background intakes of organic arsenicals. Estimates on the concentration of organic arsenicals in the diet were not located; Cohen et al. (2006) estimated that the intake of DMA from food and water is <1 ng/kg/day. As with the inorganic compounds, there are toxicological differences between these various organic derivatives; because of these differences, the discussion of the health effects of MMA, DMA, and roxarsone are discussed separately. As discussed below, animals do not appear to be good quantitative models for inorganic arsenic toxicity in humans, but it is not known if this also applies to toxicity of organic arsenicals.

Several organic arsenicals are found to accumulate in fish and shellfish. These derivatives (mainly arsenobetaine and arsenocholine, also referred to as "fish arsenic") have been studied by several researchers and have been found to be essentially nontoxic (Brown et al. 1990; Cannon et al. 1983; Charbonneau et al. 1978; Kaise et al. 1985; Luten et al. 1982; Siewicki 1981; Tam et al. 1982; Yamauchi et al. 1986). Thus, these compounds are not considered further here.

Arsine (AsH_3) and its methyl derivatives, although highly toxic, are also not considered in this profile, since these compounds are either gases or volatile liquids that are unlikely to be present at levels of concern at hazardous waste sites.

Use of Animal Data. An additional complexity to the analysis of arsenic toxicity is that most laboratory animals appear to be substantially less susceptible to inorganic arsenic than humans. For example, chronic oral exposure of humans to inorganic arsenic at doses of 0.05–0.1 mg/kg/day is frequently associated with neurological (Barton et al. 1992; Goddard et al. 1992; Guha Mazumder et al. 1988; Haupert et al. 1996; Hindmarsh et al. 1977; Huang et al. 1985; Sass et al. 1993; Silver and Wainman 1952; Szuler et al. 1979; Tay and Seah 1975; Valentine et al. 1981) or hematological signs of arsenic toxicity (Glazener et al. 1968; Guha Mazumder et al. 1988; Prasad and Rossi 1995; Sass et al. 1993; Tay and Seah 1975), but no characteristic neurological or hematological signs of arsenism were detected in monkeys, dogs, or rats chronically exposed to arsenate or arsenite at doses of 0.7–2.8 mg As/kg/day (Byron et al. 1967; EPA 1980f; Heywood and Sortwell 1979). This may be because the studies were not conducted for a sufficient length of time, or because too few animals were used. Moreover, while there is good evidence that inorganic arsenic is carcinogenic in humans by both oral and inhalation routes, evidence of inorganic arsenic-induced carcinogenicity in animals is mostly negative, with the exception of studies in mice demonstrating transplacental carcinogenesis. For these reasons, quantitative dose-response data from animals are not judged to be reliable for determining levels of significant human exposure, and will be considered only briefly except when human data are lacking.

3.2.1 Inhalation Exposure

Most information on human inhalation exposure to arsenic derives from occupational settings such as smelters and chemical plants, where the predominant form of airborne arsenic is arsenic trioxide dust. One limitation to this type of study is that exposure data are usually difficult to obtain, especially from earlier time periods when exposure levels were higher than in recent years. This is further complicated by the fact that significant oral and dermal exposures are also likely to occur under these conditions and co exposure to other metals and chemicals is also common. Thus, studies of this type are, like virtually all epidemiological studies, subject to some limitations and uncertainties. Table 3-1 and Figure 3-1 summarize studies that provide the most reliable quantitative data on health effects in humans, along with several studies in animals exposed to arsenic trioxide and other inorganic arsenic compounds by the inhalation route. Data for DMA are shown in Table 3-2 and Figure 3-2. All exposure data are expressed as milligrams of arsenic (as the element) per cubic meter of air (mg As/m^3). These studies and others that provide useful qualitative information on health effects of inorganic and organic arsenicals are discussed below.

3.2.1.1 Death

Inorganic Arsenicals. Although there are many studies of humans exposed to arsenic in air, no cases of lethality from short-term exposure were located. This suggests that death is not likely to be of concern following acute exposure, even at the very high exposure levels (1–100 mg As/m^3) found previously in the workplace (e.g., Enterline and Marsh 1982; Järup et al. 1989; Lee-Feldstein 1986). Delayed lethality from chronic exposure attributable to increased risk of cardiovascular disease or lung cancer is discussed below in Sections 3.2.1.2 and 3.2.1.7, respectively. The only report of a lethal effect of inhaled inorganic arsenic in animals was a developmental toxicology study in which four of nine pregnant rats died, and one rat was euthanized in extremis, between days 12 and 19 of gestation after 30–35 days of exposure to an aerosol of arsenic trioxide at an exposure concentration of 20 mg As/m^3 (Holson et al. 1999). These animals exhibited severe hyperemia and plasma discharge into the intestinal lumen at autopsy. In this same study, there was 100% mortality in groups of 10 pregnant rats after 1 day of exposure to concentrations ≥100 mg/m^3 (76 mg As/m^3).

Organic Arsenicals. No studies were located regarding death in humans after inhalation exposure to organic arsenicals. A 2-hour LC_{50} of 3,900 mg DMA/m^3 was calculated for DMA in female rats (Stevens et al. 1979). This LC_{50} is shown in Table 3-2 and Figure 3-2. Male rats and mice of both sexes were less susceptible, with only a few deaths after 2-hour exposures as high as 6,900 mg DMA/m^3 in rats and 6,400 mg DMA/m^3 in mice (Stevens et al. 1979). The cause of death was not specified, but was probably due to lung injury (see Section 3.2.1.2). No deaths were observed among rats and mice exposed to DSMA (the disodium salt of MMA) at concentrations up to 6,100 mg DSMA/m^3 in rats and 6,900 mg DSMA/m^3 in mice (Stevens et al. 1979). Chamber atmospheres at these high concentrations were so dense that it was difficult to see the animals clearly. These data indicate that there is no significant risk of acute lethality from concentrations of DMA or MMA that might be encountered in the environment or the workplace.

3.2.1.2 Systemic Effects

The highest NOAEL values and all reliable LOAEL values for systemic effects from inhalation exposure to inorganic arsenicals in each species and duration category are recorded in Table 3-1 and plotted in Figure 3-1, while the corresponding data for DMA are shown in Table 3-2 and Figure 3-2.

Respiratory Effects.

Inorganic Arsenicals. Workers exposed to arsenic dusts in air often experience irritation to the mucous membranes of the nose and throat. This may lead to laryngitis, bronchitis, or rhinitis (Dunlap 1921; Morton and Caron 1989; Pinto and McGill 1953), and very high exposures (characteristic of workplace exposures in the past) can cause perforation of the nasal septum (Dunlap 1921; Pinto and McGill 1953; Sandstrom et al. 1989). Despite the known respiratory irritant effects of arsenic, there have been few systematic investigations of respiratory effects in humans exposed to arsenic. Perry et al. (1948) found no difference in chest x-rays or respiratory performance (vital capacity and exercise-tolerance tests) between unexposed and exposed workers in a cross-sectional study at a factory where sodium arsenite was prepared. The NOAEL of 0.613 mg As/m^3 for respiratory effects in this study is shown in Table 3-1 and plotted in Figure 3-1.

Increased mortality due to respiratory disease has been reported in some cohort mortality studies of arsenic-exposed workers, but no conclusive evidence of an association with arsenic has been produced. In studies of workers exposed to arsenic trioxide at the Anaconda copper smelter in Montana, mortality due to noncancer respiratory disease (e.g., emphysema) was significantly increased compared to the general population (Lee-Feldstein 1983; Lubin et al. 2000; Welch et al. 1982). However, the data were not adjusted for smoking (a well-known confounder for respiratory disease), and analysis of the data with respect to arsenic exposure level did not show a clear dose-response. Similarly, Enterline et al. (1995) found a significant excess of nonmalignant respiratory disease mortality in workers at the ASARCO copper smelter in Tacoma, Washington, but only a slight negative relation to cumulative arsenic exposure. Xuan et al. (1993) found an increase in the relative risk of mortality from pneumoconiosis associated with arsenic exposure in a cohort of tin miners in China. However, this finding was based on a small number of observations (n=32), a clear exposure-response relationship with arsenic was not established, and the miners experienced confounding exposures to dust (a known risk factor for pneumoconiosis) and to radon. These studies were all considered to be inconclusive as to the relationship between inhaled inorganic arsenic and respiratory disease.

Respiratory symptoms were observed in a study of developmental effects in rats. Pregnant female rats exposed to arsenic trioxide dust starting 14 days prior to mating and continuing through mating and gestation exhibited rales at 8 mg As/m^3 and labored breathing and gasping at 20 mg As/m^3, with no symptoms at 2 mg As/m^3 (Holson et al. 1999). The lungs were examined by gross necropsy and no lesions were found. Intratracheal instillation of arsenic trioxide (13 mg As/kg) or gallium arsenide (1.5–

52 mg As/kg) can cause marked irritation and hyperplasia in the lungs of rats and hamsters (Goering et al. 1988; Ohyama et al. 1988; Webb et al. 1986, 1987). Since this sort of response is produced by a number of respirable particulate materials, it is likely that the inflammatory response is not specifically due to the arsenic.

Organic Arsenicals. No studies were located regarding respiratory effects in humans exposed to organic arsenicals. Short-term exposure of rats and mice to high concentrations (≥4,000 mg/m^3) of DMA caused respiratory distress, and necropsy of animals that died revealed bright red lungs with dark spots (Stevens et al. 1979). Respiratory distress was also observed in rats and mice exposed to high levels (≥6,100 mg/m^3) of the disodium salt of MMA (Stevens et al. 1979), although none of the MMA-exposed animals died. Respiratory distress appears to be associated with inhalation of very high concentrations of organic arsenicals. In 5-minute whole-body plethysmography trials, DMA and the disodium salt of MMA had RD_{50} (concentration calculated to produce a 50% decrease in respiration rate) values of 3,150 and 1,540 mg/m^3, respectively (Stevens et al. 1979). Based on these RD_{50} values, neither DMA nor MMA is considered to be a potent respiratory irritant. At low concentrations of DMA (34 or 100 mg DMA/m^3), an increase in intracytoplasmic eosinophilic globules were found in the nasal turbinates of rats exposed to DMA 6 hours/day, 5 days/week for 67–68 exposures (Whitman 1994).

Cardiovascular Effects.

Inorganic Arsenicals. There is some evidence from epidemiological studies that inhaled inorganic arsenic can produce effects on the cardiovascular system. Cardiovascular effects following oral exposure to arsenic are well known (see Section 3.2.2.2). A cross-sectional study of workers exposed to an estimated time-weighted average of 0.36 mg As/m^3 (as arsenic trioxide) at the Ronnskar copper smelter in Sweden for an average of 23 years showed that smelter workers had significantly increased incidences of Raynaud's phenomenon (a peripheral vascular disease characterized by spasm of the digital arteries and numbness of the fingers) and showed increased vasospasticity (constriction of blood vessels) in response to cold when tested in the fingers (Lagerkvist et al. 1986). A follow-up study conducted 2–3 years later found that vasospasticity measurements in exposed workers had improved concurrent with a reduction in arsenic exposure levels, although symptoms of peripheral vascular effects (cold hands or feet, white fingers, numbness in fingers or feet) were still common (Lagerkvist et al. 1988). A cross-sectional study including 46 workers in Denmark with varying, unquantified occupational exposure to arsenic in different occupations found that systolic blood pressure was significantly increased in the arsenic workers (median=125 mmHg) compared with controls (median=117 mmHg) (Jensen and Hansen 1998). Diastolic

pressure was also increased in this study (77.9 vs. 74.7 mmHg), although the difference from controls was not statistically significant.

Cohort mortality studies of arsenic-exposed workers at the ASARCO copper smelter in Tacoma, Washington (Enterline et al. 1995), Anaconda copper smelter in Montana (Lee-Feldstein 1983; Welch et al. 1982), Ronnskar copper smelter in Sweden (Wall 1980), orchard workers in Washington state (Tollestrup et al. 1995), and tin miners in China (Qiao et al. 1997; Xuan et al. 1993) have all reported increased risk of mortality from cardiovascular disease, specifically ischemic heart disease and cerebrovascular disease, in the cohorts studied. However, none of these studies provided conclusive evidence that the observed increase in risk was due to arsenic exposure. The studies in the ASARCO and Anaconda copper smelter workers failed to find a clear dose-response relationship with arsenic (Enterline et al. 1995; Welch et al. 1982), while a follow-up study of the Ronnskar smelter workers not only found lack of a dose-response, but also that the risk of cardiovascular disease was no longer elevated in the cohort (Järup et al. 1989). The studies in orchard workers and tin miners were limited by confounding exposures to copper, lead, and radon, respectively (Qiao et al. 1997; Tollestrup et al. 1995). The risk of cardiovascular disease mortality in the tin miners not only showed no dose-response relationship with arsenic exposure, but was positively associated with radon exposure, suggesting that radon may have been responsible for the increased cardiovascular risk in this cohort (Xuan et al. 1993).

The LOAEL for Raynaud's phenomenon and vasospasticity identified by Lagerkvist et al. (1986) is shown in Table 3-1 and Figure 3-1. No studies were located regarding cardiovascular effects in animals after inhalation exposure to inorganic arsenic.

Organic Arsenicals. No studies were located regarding cardiovascular effects in humans after inhalation exposure to organic arsenicals. No histological alterations were observed in the hearts of rats exposed to 100 mg DMA/m^3 for 67–68 exposures (Whitman 1994).

Gastrointestinal Effects.

Inorganic Arsenicals. Several case studies have reported nausea, vomiting, and diarrhea in workers with acute arsenic poisoning following occupational inhalation exposure (Beckett et al. 1986; Bolla-Wilson and Bleecker 1987; Ide and Bullough 1988; Morton and Caron 1989; Pinto and McGill 1953). Although gastrointestinal effects are not typically associated with arsenic poisoning by inhalation (Pinto and McGill 1953), such effects are a common feature of oral ingestion of high doses of arsenic (see Section 3.2.2.2),

and it is possible that mucociliary transport of arsenic dust from the lungs to the gut could be responsible for the effects in these cases. Exposure levels were not reliably estimated for any of these cases.

The only report of gastrointestinal effects of inhaled inorganic arsenic in animals was a developmental toxicology study in which four of nine pregnant rats died, and one rat was euthanized *in extremis*, between days 12 and 19 of gestation after 30–35 days of exposure to an aerosol of arsenic trioxide at an exposure concentration of 20 mg As/m^3 (Holson et al. 1999). These animals exhibited severe hyperemia and plasma discharge into the intestinal lumen at autopsy. Exposure to 8 mg As/m^3 did not produce gross gastrointestinal lesions.

Organic Arsenicals. Data regarding gastrointestinal effects in people exposed to organic arsenic in the air are limited. The frequency of gastrointestinal complaints was no higher than controls in workers exposed to arsanilic acid (i.e., 4-aminophenyl arsonic acid) at mean concentrations up to 0.17 mg/m^3 in a chemical factory (Watrous and McCaughey 1945). However, this sort of data might easily be biased by workers who chose not to complain about minor symptoms, so no conclusion can be reached. Rats and mice exposed to very high levels (above 3,000 mg/m^3) of MMA (disodium salt) or DMA experienced diarrhea (Stevens et al. 1979). The diarrhea could be due to transport of inhaled particulate material from the lungs to the gastrointestinal system or to direct ingestion of the compound (e.g., from grooming of the fur). No gastrointestinal effects were observed in rats repeatedly exposed to 100 mg DMA/m^3 6 hours/day, 5 days/week for 67–68 exposures (Whitman 1994).

Hematological Effects.

Inorganic Arsenicals. Although anemia is a common feature of arsenic poisoning following oral exposure in humans (see Section 3.2.2.2), case studies of workers with arsenic poisoning from occupational inhalation exposure reported no effects on red blood cell count (Beckett et al. 1986; Bolla-Wilson and Bleecker 1987; Ide and Bullough 1988; Morton and Caron 1989). The reason for this apparent route specificity is not clear, but might simply be related to dose. No studies were located regarding hematological effects in animals after inhalation exposure to inorganic arsenicals.

Organic Arsenicals. No effect on levels of hemoglobin, red cells, or white cells was detected in the blood of manufacturing workers (323 counts in 35 workers) exposed to airborne arsanilic acid dusts at a mean concentration of 0.17 mg/m^3 in the workplace (Watrous and McCaughey 1945). Controls were an unspecified number of unexposed manufacturing workers with 221 complete blood counts. No

hematological alterations were observed in rats exposed to 100 mg DMA/m^3 for an intermediate duration (Whitman 1994).

Musculoskeletal Effects.

Inorganic Arsenicals. Few data were located regarding musculoskeletal effects associated with inhalation exposure to inorganic arsenic, and none to suggest the existence of any such effects. Electromyographic examination of the calves and feet showed no differences between control and arsenic-exposed workers in a cross-sectional study of workers at the Ronnskar copper smelter in Sweden (Blom et al. 1985). No studies were located regarding musculoskeletal effects in animals after inhalation exposure to inorganic arsenicals.

Organic Arsenicals. No studies were located regarding musculoskeletal effects in humans or animals after inhalation exposure to organic arsenicals.

Hepatic Effects.

Inorganic Arsenicals. There is no evidence that inhaled inorganic arsenic produces effects on the liver, although few data are available. Case studies of workers with inhalation arsenic poisoning that included liver function tests did not find any evidence of hepatic dysfunction (Bolla-Wilson and Bleecker 1987; Ide and Bullough 1988). No studies were located regarding hepatic effects in animals after inhalation exposure to inorganic arsenicals.

Organic Arsenicals. No studies were located regarding hepatic effects in humans after inhalation exposure to organic arsenicals. No histological alterations were observed in the livers of rats exposed to 100 mg DMA/m^3 for 67–68 exposures (Whitman 1994).

Renal Effects.

Inorganic Arsenicals. The limited data available do not suggest any relationship between inhalation of inorganic arsenic and kidney effects. A cross-sectional study of renal function parameters in glass factory workers exposed to arsenic (concentrations unknown) found no meaningful differences from controls in urinary levels of several proteins (albumin, retinol binding protein, β_2-microglobulin, brush-border antigen) used as markers of glomerular damage or tubular cell exfoliation (Foà et al. 1987). Routine

clinical urinalysis was normal when included in case studies of workers with inhalation arsenic poisoning (Ide and Bullough 1988; Morton and Caron 1989). No studies were located regarding renal effects in animals after inhalation exposure to inorganic arsenicals.

Organic Arsenicals. No studies were located regarding renal effects in humans after inhalation exposure to organic arsenicals. No renal effects were reported in rats exposed to 100 mg DMA/m^3 6 hours/day, 5 days/week for 67–68 exposures (Whitman 1994).

Dermal Effects.

Inorganic Arsenicals. Dermatitis has frequently been observed in industrial workers exposed to inorganic arsenic in the air, with the highest rates occurring in the workers with the greatest arsenic exposure (Cöl et al. 1999; Dunlap 1921; Holmqvist 1951; Lagerkvist et al. 1986; Pinto and McGill 1953). Limited quantitative information is available regarding the exposure levels that produce dermatitis, and the high likelihood of co-exposure by the dermal route makes dose-response analysis difficult. A cross-sectional study of workers at a factory where sodium arsenite was prepared found that workers with the highest arsenic exposure (mean air levels ranging from 0.384 to 1.034 mg As/m^3 and estimated to average 0.613 mg As/m^3) tended to be grossly pigmented with hyperkeratinization of exposed skin and to have multiple warts (Perry et al. 1948). In the same study, workers with lower arsenic exposure (estimated to average 0.078 mg As/m^3) were much less affected, but still had a higher incidence of pigmentation keratosis than controls. LOAEL values identified by Perry et al. (1948) and Mohamed (1998) are shown in Table 3-1 and Figure 3-1. NOAEL values for dermal irritation have not been identified. Dermal effects (hyperkeratoses, hyperpigmentation) are also very common in people exposed to inorganic arsenic by the oral route (see Section 3.2.2.2). No studies were located on dermal effects in animals after inhalation exposure to inorganic arsenicals.

Organic Arsenicals. Data regarding dermal effects in people exposed to organic arsenic in the air are limited. Complaints of keratosis were roughly 2-fold higher than unexposed controls in female packaging workers exposed to arsanilic acid at an average concentration of 0.065 mg/m^3 and in male manufacturing workers exposed to an average concentration of 0.17 mg/m^3 in a chemical factory (Watrous and McCaughey 1945). Limitations in study methodology (e.g., alternate sources of effects were not investigated, workers might choose not to report minor complaints to company officials) make the reliability of this observation uncertain. Female rats exposed to DMA at 6,900 mg/m^3 developed erythematous lesions on the feet and ears (Stevens et al. 1979); these lesions did not develop in females

exposed at lower concentrations (4,100 mg/m^3) or males. It seems likely that these effects were due to direct irritation from dermal contact with the dust. No dermal effects were observed in rats repeatedly exposed to lower levels of DMA (100 mg/m^3) (Whitman 1994).

Ocular Effects.

Inorganic Arsenicals. Chemical conjunctivitis, characterized by redness, swelling, and pain, has been observed in workers exposed to arsenic dusts in air, usually accompanied by facial dermatitis (Dunlap 1921; Pinto and McGill 1953). No information was located regarding air levels of arsenic that produce this effect. No studies were located on ocular effects in animals after inhalation exposure to inorganic arsenicals.

Organic Arsenicals. No studies were located on ocular effects in humans after inhalation exposure to organic arsenicals. Rats and mice exposed to high concentrations of DMA (≥4,000 mg/m^3) developed an encrustation around the eyes (Stevens et al. 1979). It seems likely that these effects were due to direct irritation from ocular contact with the dust.

Body Weight Effects.

Inorganic Arsenicals. No studies were located on body weight effects in humans after inhalation exposure to inorganic arsenicals. Female rats exposed to arsenic trioxide dust starting 14 days before mating and continuing through mating and gestation showed a marked decrease in body weight and food consumption at 20 mg As/m^3 (preliminary study) and a smaller decrease at 8 mg As/m^3 (definitive study), with no effect at 2 mg As/m^3 (Holson et al. 1999).

Organic Arsenicals. No studies were located on body weight effects in humans after inhalation exposure to organic arsenicals. Rats and mice exposed to high concentrations of DMA (≥4,000 mg/m^3) for 2 hours had an unspecified decrease in body weight gain during the subsequent 14 days (Stevens et al. 1979). No alterations in body weight gain were observed in rats exposed to 100 mg DMA/m^3 for 67–68 exposures (Whitman 1994).

3.2.1.3 Immunological and Lymphoreticular Effects

Inorganic Arsenicals. A single study was located regarding the immunological and lymphoreticular effects of inhaled inorganic arsenic in humans. Bencko et al. (1988) detected no abnormalities in serum levels of immunoglobins in 47 workers exposed to arsenic (exposure levels not measured) in a coal-burning power plant. However, serum levels of other proteins such as transferrin, orosomucoid, and ceruloplasmin were significantly elevated compared to levels in a group of 27 workers from a different plant in which the arsenic content in the coal was 10 times lower. The investigators suggested that the increased levels of ceruloplasmin might be related to higher cancer mortality rates found among these workers.

The immune effects of inhaled arsenic in animals were studied by Aranyi et al. (1985). Female mice exposed to arsenic trioxide aerosol for 3 hours showed a concentration-related decrease in pulmonary bactericidal activity (presumably as a result of injury to alveolar macrophages) and a corresponding concentration-related increase in susceptibility to introduced respiratory bacterial pathogens. Similar results were found when the exposure was repeated over 1- and 4-week periods. The NOAEL and LOAEL values for this study are shown in Table 3-1 and Figure 3-1.

Intratracheal studies in animals offer some support for an immune effect of inhaled inorganic arsenic. Decreases in humoral response to antigens and in several complement proteins were noted in mice given an intratracheal dose of 5.7 mg As/kg as sodium arsenite (Sikorski et al. 1989), although these changes were not accompanied by any decrease in resistance to bacterial or tumor cell challenges. Animals given an intratracheal dose of GaAs (25 mg As/kg or higher) also displayed a variety of changes in numerous immunological end points (some increased, some decreased) (Burns and Munson 1993; Sikorski et al. 1989). Whether these effects were due to a direct effect on the immune system or were secondary to the inflammatory effect of GaAs on the lung (see Section 3.2.1.2, above) is uncertain.

Organic Arsenicals. No studies were located regarding immunological and lymphoreticular effects in humans or animals after inhalation exposure to organic arsenicals.

3.2.1.4 Neurological Effects

Inorganic Arsenicals. There is evidence from epidemiological studies that inhaled inorganic arsenic can produce neurological effects. A study by Gerr et al. (2000) reported an elevated incidence of peripheral neuropathy in subjects who lived near an arsenic-using pesticide plant (13/85=15.3%; odds ratio

[OR]=5.1, p=0.004), relative to subjects who lived farther from the plant (4/118=3.4%). Concentrations of arsenic in soil and house dust were elevated (~30–300 µg As/g) for residences near the plant, according to 1993–1995 monitoring data. Studies of copper smelter workers at the ASARCO smelter in Tacoma, Washington (Feldman et al. 1979), a power station in Slovakia (Buchancová et al. 1998), and the Ronnskar smelter in Sweden (Blom et al. 1985; Lagerkvist and Zetterlund 1994) have demonstrated peripheral neurological effects in workers associated with arsenic trioxide exposure. At the ASARCO smelter, the prevalence of clinically diagnosed peripheral neuropathy was markedly higher in arsenic-exposed workers (26/61=43%) than controls (4/33=12%), and although the difference in mean nerve conduction velocities (NCV) was not statistically significant, mean peroneal motor NCV was lower in arsenic-exposed workers than controls and all 12 cases of abnormally low NCV occurred in the arsenic group (Feldman et al. 1979). In the study of 70 workers in Slovakia, the investigators described 16 cases of arsenic intoxication. Among these, 13 had signs and symptoms of sensory and motor polyneuropathy on both upper and lower extremities, 10 were diagnosed with pseudoneurasthenic syndrome, and 6 suffered from toxic encephalopathy (Buchancová et al. 1998). The average length of exposure was 22.3 years (SD ±8.4 years) and the average arsenic exposure in inhaled air ranged from 4.6 to 142.7 µg/m^3. Similar results were observed at the Ronnskar smelter, where Blom et al. (1985) reported significantly increased prevalence of workers with abnormally low NCV in the exposed group, and lower, but not statistically significant, mean NCV in five peripheral nerves. A follow-up study on the Ronnskar workers 5 years later found that the prevalence of abnormally low NCV remained significantly increased in the exposed workers, but that the decrease in mean NCV was now also statistically significant in the tibial (motor) and sural (sensory) nerves (Lagerkvist and Zetterlund 1994). Blood lead was monitored in this study as a potential confounder, but levels were low and not considered likely by the researchers to have had any influence on the results. The follow-up Ronnskar study provided enough information to estimate that mean arsenic exposure was 0.31 mg As/m^3 and lasted an average of 28 years in the exposed group, and this LOAEL is shown in Table 3-1 and Figure 3-1.

The literature also contains several case studies of workers with inhalation arsenic poisoning who developed neurological symptoms. Although these studies do not provide reliable information on exposure levels or conclusive evidence that the observed effects were related to arsenic, the findings are suggestive. Symptoms in these cases included not only indicators of peripheral neuropathy (numbness, loss of reflexes, muscle weakness, tremors) (Ide and Bullough 1988; Morton and Caron 1989), but also frank encephalopathy (hallucinations, agitation, emotional lability, memory loss) (Beckett et al. 1986; Bolla-Wilson and Bleecker 1987; Morton and Caron 1989). Both peripheral neuropathy and encephalopathy are associated with oral exposure to inorganic arsenic (see Section 3.2.2.4).

The possible association between arsenic in air and neurological effects in children has also been examined. A study by Bencko et al. (1977) reported that children of approximately 10 years of age (n=56) living near a power plant burning coal of high arsenic content showed significant hearing losses (increased threshold) compared to a control group of children (n=51) living outside the polluted area (Bencko et al. 1977). The effect was most marked at low frequencies. The precise site affected within the auditory pathway was not determined and could have been in the periphery, centrally-located, or both. A small study of children in Mexico reported a significant negative correlation between tests of verbal IQ and urinary arsenic in children (n=41) living in an urban area near a smelter complex (Calderón et al. 2001). Exposure concentrations were not available in either study.

No studies were located regarding neurological effects in animals after inhalation exposure to inorganic arsenicals. Mice given a single intratracheal dose of 200 mg/kg of GaAs displayed a decrease in overall activity 6–8 hours later, but no additional neurological evaluations were conducted on these animals (Burns and Munson 1993).

Organic Arsenicals. Data regarding neurological effects in people exposed to organic arsenic in the air are limited to a single study. The frequency of central nervous system complaints was no higher than controls in workers at a chemical factory exposed to arsanilic acid at mean concentrations up to 0.17 mg/m^3 (Watrous and McCaughey 1945). Although peripheral nerve complaints were higher in arsenic packaging workers (mean exposure=0.065 mg/m^3) than in unexposed controls, this was not the case in manufacturing workers with higher arsenic exposure (mean=0.17 mg/m^3). This suggests that the effects on the peripheral nerves in the exposed packaging workers were not due to arsenic. The reliability of these data is limited by shortcomings in the study methodology (e.g., the data might easily be biased by workers who chose not to complain about minor symptoms). No studies were located regarding neurological effects in animals after inhalation exposure to organic arsenicals.

3.2.1.5 Reproductive Effects

Inorganic Arsenicals. No studies were located regarding reproductive effects in humans after inhalation exposure to inorganic arsenicals. Reproductive performance was evaluated in female rats exposed to 0.08–20 mg As/m^3 (preliminary study) or 0.2–8 mg As/m^3 (definitive study) as As_2O_3 6 hours daily from 14 days prior to mating through gestation day 19 (Holson et al. 1999). No changes occurred in the precoital interval (time to mating), mating index (percentage of rats mated), or fertility index (percentage

of matings resulting in pregnancy). The NOAEL values for this study are shown in Table 3-1 and Figure 3-1.

Organic Arsenicals. No studies were located regarding reproductive effects in humans or animals after inhalation exposure to organic arsenicals.

3.2.1.6 Developmental Effects

Inorganic Arsenicals. Developmental effects associated with occupational and environmental exposure to airborne arsenic have been investigated in a series of studies at the Ronnskar copper smelter in northern Sweden (Nordström et al. 1978a, 1978b, 1979a, 1979b). In comparison to a northern Swedish reference population, female employees of the smelter had a significantly increased incidence of spontaneous abortion (Nordström et al. 1979a), and their children had a significantly increased incidence of congenital malformations (Nordström et al. 1979b) and significantly decreased average birth weight (Nordström et al. 1978a). Increased incidence of spontaneous abortion and decreased average birth weight of children were also found in populations living in close proximity to the smelter (Nordström et al. 1978a, 1978b, 1979b). While these data are suggestive of developmental effects associated with occupational and environmental exposure from the smelter, the reported effects are not large, the analyses include only limited consideration of potential confounders (e.g., smoking), and there are no data relating the apparent effects specifically to arsenic exposure.

Ihrig et al. (1998) conducted a case-control study of stillbirths in the vicinity of a Texas arsenic pesticide factory that included estimation of environmental arsenic exposures using atmospheric dispersion modeling and multiple regression analysis considering arsenic exposure, race/ethnicity, maternal age, median income, and parity as explanatory variables. There was a statistically significant increase in the risk of stillbirth in the highest exposure category (>100 ng As/m^3, midpoint=682 ng/m^3). Further analysis showed that this increase in risk was limited to people of Hispanic descent, who the researchers speculated may be an especially sensitive population due to a genetic impairment in folate metabolism. Interpretation of this study is limited by small numbers of cases and controls in the high exposure group, lack of data on smoking, potential confounding exposures to other chemicals from the factory, and failure to take into account previous years of deposition in the exposure estimates.

Arsenic has been shown to produce developmental effects by inhalation exposure in laboratory animals, although it is unclear whether or not the effects occur only at maternally toxic doses. Mice exposed to

22 mg As/m^3 (as As_2O_3) for 4 hours on days 9–12 of gestation had serious developmental effects (significant increases in the percentage of dead fetuses, skeletal malformations, and the number of fetuses with retarded growth), while those exposed to 2.2 mg As/m^3 had only a 10% decrease in average fetal body weight, and those exposed to 0.20 mg As/m^3 had no effects (Nagymajtényi et al. 1985). The study was limited by failure to quantify malformations on a litter basis, discuss the nature and severity of the observed malformations, or report on the occurrence of maternal effects. No increases in fetal resorptions, fetal mortality, or malformations, and no decreases in fetal body weight occurred when rats were exposed to 0.2–8 mg As/m^3 (as As_2O_3), 6 hours daily from 14 days prior to mating through gestation day 19 (Holson et al. 1999). At the 8 mg/m^3 exposure level, toxicity was observed in the dams, including rales, a dried red exudate at the nose, and lower gains in net body weight than controls. In a preliminary dose-range study, there was a marked significant increase in postimplantation loss (primarily early resorptions) and consequent marked significant decrease in viable fetuses per litter at 20 mg As/m^3, a concentration that also produced severe maternal effects including mortality (Holson et al. 1999).

The NOAEL and LOAEL values for increased risk of stillbirth in humans identified by Ihrig et al. (1998) and those for developmental effects in rodents found by Nagymajtényi et al. (1985) and Holson et al. (1999) are shown in Table 3-1 and Figure 3-1.

Organic Arsenicals. No studies were located regarding developmental effects in humans or animals after inhalation exposure to organic arsenicals.

3.2.1.7 Cancer

Inorganic Arsenicals. There is convincing evidence from a large number of epidemiological studies that inhalation exposure to inorganic arsenic increases the risk of lung cancer. Most studies involved workers exposed primarily to arsenic trioxide dust in air at copper smelters (Axelson et al. 1978; Brown and Chu 1982, 1983a, 1983b; Enterline and Marsh 1982; Enterline et al. 1987a, 1987b, 1995; Ferreccio et al. 1996; Järup and Pershagen 1991; Järup et al. 1989; Lee and Fraumeni 1969; Lee-Feldstein 1983, 1986; Lubin et al. 2000; Mazumdar et al. 1989; Pinto et al. 1977, 1978; Sandstrom et al. 1989; Viren and Silvers 1999; Wall 1980; Welch et al. 1982) and mines (Liu and Chen 1996; Qiao et al. 1997; Taylor et al. 1989; Xuan et al. 1993), but increased incidence of lung cancer has also been observed at chemical plants where exposure was primarily to arsenate (Bulbulyan et al. 1996; Mabuchi et al. 1979; Ott et al. 1974; Sobel et al. 1988). In addition, several studies suggest that residents living near smelters or arsenical chemical plants may also have increased risk of lung cancer (Brown et al. 1984; Cordier et al. 1983; Matanoski et

al. 1981; Pershagen 1985), although the increases are small and are not clearly detectable in all cases (e.g., Frost et al. 1987). The strongest evidence that arsenic is responsible for the observed lung cancer comes from quantitative dose-response data relating specific arsenic exposure levels to lung cancer risk. These data are available for arsenic-exposed workers at the ASARCO copper smelter in Tacoma, Washington (Enterline and Marsh 1982; Enterline et al. 1987a, 1995; Mazumdar et al. 1989), the Anaconda copper smelter in Montana (Lee-Feldstein 1986; Welch et al. 1982), eight other U.S. copper smelters (Enterline et al. 1987b), and the Ronnskar copper smelter in Sweden (Järup and Pershagen 1991; Järup et al. 1989). A common limitation of these studies is confounding exposure to other chemicals, such as sulfur dioxide, and cigarette smoking.

Enterline and Marsh (1982) reported a significant increase in respiratory cancer mortality (standard mortality ratio [SMR]=189.4) based on 104 observed respiratory cancer deaths and only 54.9 expected over the years 1941–1976 in a cohort of 2,802 male workers employed for ≥1 year between 1940 and 1964 at the ASARCO smelter. When the cohort was separated into low and high arsenic exposure groups, with mean estimated time-weighted average arsenic exposures of 0.054 and 0.157 mg As/m^3, respectively (based on work history, historical urinary arsenic measurements, and an experimentally derived relationship between urinary and inhaled arsenic), respiratory cancer mortality was significantly increased in both groups in a concentration-related fashion (SMR=227.7 and 291.4 in the low and high groups, respectively). Enterline et al. (1987a) re-analyzed these data using improved exposure estimates that incorporated historical measurements of arsenic in the ambient air and personal breathing zone of workers. Respiratory cancer mortality was significantly increased in a concentration-related fashion in the low (SMR=213.0), medium (SMR=312.1), and high (SMR=340.9) arsenic exposure groups, which had mean estimated time-weighted average arsenic exposures of 0.213, 0.564, and 1.487 mg As/m^3, respectively. An alternative analysis of these data by Mazumdar et al. (1989) produced similar results. Enterline et al. (1995) extended the mortality follow-up from 1976 to 1986, but reported findings similar to the earlier study in a less thorough analysis. The CEL from Enterline et al. (1987a), the most complete analysis of the ASARCO cohort with the best exposure estimates, is presented in Table 3-1 and Figure 3-1.

Respiratory cancer mortality was significantly increased (SMR=285) based on 302 observed respiratory deaths between 1938 and 1977 in a cohort of 8,045 white male workers employed for at least 1 year between 1938 and 1956 at the Anaconda smelter (Lee-Feldstein 1986). When workers were categorized according to cumulative arsenic exposure and date of hire, lung cancer mortality was significantly increased in all groups hired between 1925 and 1947. Workers in the lowest cumulative exposure group

(<10 mg-mo/m^3) were reported to have had <2 years of exposure at an average arsenic concentration of 0.38 mg/m^3. An alternative analysis of a subset of the Anaconda cohort (n=1,800, including all 277 employees with heavy arsenic exposure and 20% of the others) that included information on smoking and other occupational exposures was performed by Welch et al. (1982). This analysis showed that lung cancer mortality increased with increasing time-weighted average arsenic exposure, with a small nonsignificant increase in the low group (SMR=138) exposed to 0.05 mg/m^3 and significant increases in the medium (SMR=303), high (SMR=375), and very high (SMR=704) groups exposed to 0.3, 2.75, and 5.0 mg/m^3, respectively. Cohort members were more likely to be smokers than U.S. white males, but smoking did not differ among the arsenic exposure groups. Exposure-response analysis of smokers was similar to the analysis based on the full subcohort, while analysis of nonsmokers (limited by small group sizes) also showed a similar pattern, but with lower SMRs. In a followup analysis of the same cohort, Lubin et al. (2000) re-weighted the exposure concentrations based on duration and time of exposure and re-evaluated the effects of exposure. Relative risks for respiratory cancer increased with increasing duration in each arsenic exposure area (light, medium, and heavy) after adjustment for duration in the other two exposure areas. SMRs were significantly elevated following exposure to 0.58 mg/m^3 (medium; SMR=3.01, 95% CI=2.0–4.6) or 11.3 mg/m^3 (high; SMR=3.68, 95% CI=2.1–6.4) for 10 or more years, and following exposure to 0.29 mg/m^3 (low; SMR=1.86, 95% CI=1.2–2.9) for 25 or more years. The CELs from the analyses of the Anaconda cohort are presented in Table 3-1 and Figure 3-1.

Enterline et al. (1987b) studied the mortality experience from 1949 to 1980 of a cohort of 6,078 white males who had worked for 3 years or more between 1946 and 1976 at one of eight U.S. copper smelters in Arizona, Utah, Tennessee, and Nevada. Lung cancer mortality was significantly increased only in the Utah smelter (SMR=226.7), which had the highest average arsenic exposure concentration (0.069 mg/m^3 vs. 0.007–0.013 mg/m^3 in the other smelters) and also contributed the largest number of cohort members (n=2,288 vs. 189–965 from the other smelters). A nested case-control study showed that arsenic exposure and cigarette smoking were significant risk factors for lung cancer in the smelter workers. Smoking was lower in the Utah smelter workers than in the other smelter workers, but still higher than in the referent Utah population, suggesting that the risk attributable to arsenic in this study population is somewhat lower than indicated by the SMR reported above. The CEL from this study is presented in Table 3-1 and Figure 3-1.

Järup et al. (1989) reported significantly increased lung cancer mortality (SMR=372, 95% confidence interval [CI]=304–450) based on 106 lung cancer deaths in a cohort of 3,916 male workers employed for ≥3 months between 1928 and 1967 at the Ronnskar smelter and followed for mortality through 1981.

Workers were separated into low, medium, and high arsenic exposure groups with mean time-weighted average exposure estimates of 0.05, 0.2, and 0.4 mg/m^3, respectively. Lung cancer mortality was significantly increased in all three exposure groups in a concentration-related fashion (SMR=201, 353, and 480, respectively). A nested case-control analysis of 102 lung cancer cases and 190 controls from the cohort showed that lung cancer risk increased with increasing arsenic exposure in nonsmokers, light smokers, and heavy smokers (Järup and Pershagen 1991). The results demonstrated that arsenic is a risk factor for lung cancer in the smelter workers, but also suggested a greater-than-additive interaction between smoking and arsenic exposure. In this analysis, in contrast to the cohort study, lung cancer risk due to arsenic was increased only in the higher arsenic-exposure groups. Potential explanations for this difference between the cohort and case-control analyses include a higher proportion of smokers in the smelter workers than in the regional referent population in the cohort study, and limited power to detect increased risk in the case-control study due to small group sizes in the dose-response analysis. The CELs from both the cohort and case-control studies are presented in Table 3-1 and Figure 3-1.

Several researchers have examined the histological cell types of lung cancer (epidermoid carcinoma, small cell carcinoma, adenocarcinoma) in arsenic-exposed workers (e.g., Axelson et al. 1978; Newman et al. 1976; Pershagen et al. 1987; Qiao et al. 1997; Wicks et al. 1981). Although the incidence of the various cell types varied from population to population, all studies found an increase in several tumor types. This indicates that arsenic does not specifically increase the incidence of one particular type of lung cancer.

The studies of the ASARCO cohort (Enterline and Marsh 1982; Enterline et al. 1987a, 1995) noted a supralinear exposure-response relationship (i.e., steeper at lower doses) between arsenic exposure and lung cancer mortality. Hertz-Picciotto and Smith (1993) extended this observation to several other occupationally exposed cohorts with quantitative exposure information. The authors suggest that neither toxicokinetic mechanisms nor confounding from age, smoking, or other workplace carcinogens that differ by exposure level are likely explanations for the curvilinearity. Plausible explanations offered include: (1) synergism (with smoking), which varies in magnitude according to the level of arsenic exposure, (2) long-term survivorship at higher exposures among the healthier, less susceptible individuals, and (3) exposure estimate errors that were more prominent at higher-exposure levels as a result of past industrial hygiene sampling or worker protection practices.

Quantitative risk estimates for inhaled inorganic arsenic have been derived using the exposure-response data. EPA derived a unit risk estimate (the excess risk of lung cancer associated with lifetime exposure to

1 μg/m^3) of 4.3x10^{-3} per (μg/m^3) based on the dose-response relationships between arsenic exposure and excess lung cancer mortality in workers at the Anaconda smelter in Montana (Brown and Chu 1982, 1983a, 1983b; Lee-Feldstein 1983; and an unpublished paper by Higgins and associates) and the ASARCO smelter in Tacoma, Washington (Enterline and Marsh 1982; EPA 1984a; IRIS 2007). In some cases, calculations of exposure, as well as the procedures for generating quantitative risk estimates, are quite complex and the interested reader is referred to the EPA documents (EPA 1981c, 1984a, 1987e, 1996b; IRIS 2007) for a detailed description. Viren and Silvers (1994) re-evaluated the unit risk estimate using the same methods as EPA, but incorporating updated results from the ASARCO smelter (Enterline et al. 1987a; Mazumdar et al. 1989) and the findings from the Swedish smelter (Järup et al. 1989). Their analysis yielded a revised unit risk of 1.28x10^{-3} per (μg/m^3) that, when pooled with the earlier estimate from the Montana smelter cohort, yielded a composite unit risk of 1.43x10^{-3} per (μg/m^3). This unit risk estimate is a factor of 3 smaller than the EPA's current estimate of 4.3x10^{-3} per (μg/m^3). Figure 3-1 shows the air concentrations that correspond to excess lifetime cancer risks of 10^{-4}–10^{-7} based on the EPA unit risk estimate.

There have been occasional reports of other types of cancer (i.e., nonrespiratory cancer) potentially associated with inhalation exposure to inorganic arsenic, but there is no strong evidence for any of them. For example, Enterline et al. (1995) found significantly increased mortality due to cancer of the large intestine and bone cancer in the ASARCO cohort. However, neither cancer showed any relation to cumulative arsenic exposure, and the purported increase in bone cancer risk was based on a very small number of observations. Pesch et al. (2002) reported an increase in nonmelanoma skin cancers resulting from exposure from a Slovakian coal-burning power plant, but exposure levels associated with the lesions were not presented. Bencko et al. (2005) also reported an increase in the incidence of nonmelanoma skin cancer among workers of a power plant burning coal of a high arsenic content and in the population living in the vicinity of the power plant. Bulbulyan et al. (1996) reported an increase in risk of stomach cancer among workers exposed to the highest average arsenic concentrations at a Russian fertilizer plant, but this finding, which was based on a small number of observations and was only marginally statistically significant, was confounded by exposure to nitrogen oxides, which were more convincingly associated with stomach cancer in this study. Wingren and Axelson (1993) reported an association between arsenic exposure and stomach and colon cancer in Swedish glass workers, but this result was confounded by concomitant exposure to other metals. Lee-Feldstein (1983) observed a small, marginally significant increase in digestive tract cancer (SMR=125) in one study of the Anaconda cohort, but this was not found in other studies of this cohort (Lee and Fraumeni 1969; Lee-Feldstein 1986; Welch et al. 1982). Wulff et al. (1996) observed an apparent increase in the risk of childhood cancer (all types combined) in the

population living within 20 km of the Ronnskar smelter, but the apparent increase was based on a small number of cases (13 observed vs. 6.7 expected) and was not statistically significant, and exposure to arsenic was confounded by exposure to lead, copper, cadmium, sulfur dioxide, and possibly other emissions such as nickel and selenium. A retrospective study of deaths due to unspecified types of malignancies among workers of power plants found no significant differences in death rate between two groups whose exposure levels to arsenic had a difference of one order of magnitude (Bencko et al. 1980). However, the mean age of those deceased due to cancer in the high-exposure group was 55.9 years compared to 61.2 years in the low-exposure group, and this difference was statistically significant ($p<0.05$). Also, when the workers were stratified by exposure-duration, there was a significantly higher frequency of tumors in the high-exposure group after shorter employment periods (<5 or 6–10 years) than after a longer employment period (≥11 years). No information was provided regarding specific types of cancer. Various case reports have implicated occupational arsenic exposure as a potential contributing factor in workers who developed sinonasal cancer (Battista et al. 1996), hepatic angiosarcoma (Tsai et al. 1998a), and skin cancer (Cöl et al. 1999; Tsuruta et al. 1998), but provide no proof that inhaled arsenic was involved in the etiology of the observed tumors. Wong et al. (1992) found no evidence that environmental exposure to airborne arsenic produced skin cancer in residents living near the Anaconda smelter or an open pit copper mine.

No studies were located regarding cancer in animals after inhalation exposure to inorganic arsenicals, although several intratracheal instillation studies in hamsters have provided evidence that both arsenite and arsenate can increase the incidence of lung adenomas and/or carcinomas (Ishinishi et al. 1983; Pershagen and Björklund 1985; Pershagen et al. 1984; Yamamoto et al. 1987). These data support the conclusion that inhalation of arsenic may lead to lung cancer in humans.

Organic Arsenicals. No studies were located regarding cancer effects in humans or animals after inhalation exposure to organic arsenicals.

3.2.2 Oral Exposure

There are a large number of studies in humans and animals on the toxic effects of ingested arsenic. In humans, most cases of toxicity have resulted from accidental, suicidal, homicidal, or medicinal ingestion of arsenic-containing powders or solutions or by consumption of contaminated food or drinking water. In some cases, the chemical form is known (e.g., the most common arsenic medicinal was Fowler's solution, which contained 1% potassium arsenite or arsenic trioxide), but in many cases (e.g., exposures through

drinking water), the chemical form is not known. In these cases, it is presumed that the most likely forms are either inorganic arsenate [As(+5)], inorganic arsenite [As(+3)], or a mixture. Table 3-3 and Figure 3-3 summarize a number of studies that provide reliable quantitative data on health effects in humans and animals exposed to inorganic arsenicals by the oral route. Similar data for MMA, DMA, and roxarsone are listed in Tables 3-4, 3-5, and 3-6, and shown in Figures 3-4, 3-5, and 3-6, respectively. All exposure data are expressed as milligrams of arsenic (as the element) per kilogram body weight per day (mg As/kg/day). These studies and others that provide useful qualitative information are summarized below.

3.2.2.1 Death

Inorganic Arsenicals. There are many case reports of death in humans due to ingestion of high doses of arsenic. In nearly all cases, the most immediate effects are vomiting, diarrhea, and gastrointestinal hemorrhage, and death may ensue from fluid loss and circulatory collapse (Levin-Scherz et al. 1987; Saady et al. 1989; Uede and Furukawa 2003). In other cases, death may be delayed and result from the multiple tissue injuries produced by arsenic (Campbell and Alvarez 1989). Some accounts of fatal arsenic poisoning describe both gastrointestinal effects soon after ingestion and extensive damage to multiple organ systems prior to death (Quatrehomme et al. 1992). A precise estimate of the ingested dose is usually not available in acute poisonings, so quantitative information on lethal dose in humans is sparse. The lethal doses ranged from 22 to 121 mg As/kg in four cases where known amounts were ingested as a single bolus (Civantos et al. 1995; Hantson et al. 1996; Levin-Scherz et al. 1987; Quatrehomme et al. 1992). Two people in a family of eight died from ingestion of water containing about 110 ppm of arsenic for a week (Armstrong et al. 1984). This corresponded to a dose of about 2 mg As/kg/day. Based on a review of clinical reports in the older literature, Holland (1904) estimated the minimum lethal dose to be about 130 mg (also about 2 mg/kg). A similar estimate of 70–180 mg (about 1–3 mg/kg) was provided by Vallee et al. (1960). Death due to chronic arsenic exposure has been reported at lower concentrations. Five children between the ages of 2 and 7 years died from late sequelae of chronic arsenic poisoning after drinking contaminated water throughout their lives at estimated average doses of 0.05–0.1 mg As/kg/day (Zaldívar and Guillier 1977). A 22-year-old man with chronic arsenical dermatosis died from arsenic-related effects after lifetime exposure to an estimated average dose of 0.014 mg As/kg/day in the drinking water (Zaldívar et al. 1981). Systematic studies of lethality from chronic exposure attributable to increased risk of cardiovascular disease or cancer are discussed below in Sections 3.2.2.2 and 3.2.2.7, respectively.

Chronic (≥365 days)

REC 5626

Available LD_{50} values for arsenate and arsenite in rats and mice range from 15 to 175 mg As/kg (Dieke and Richter 1946; Gaines 1960; Harrisson et al. 1958; Kaise et al. 1985). The variability can be attributed to differences based on species, strain, specific route of exposure (feed vs. gavage), specific compound tested, and testing laboratory. Most deaths occurred within 1 day of exposure, but details regarding cause of death were not generally reported. Seven of 25 pregnant rats given a single gavage dose of 23 mg As/kg as arsenic trioxide on day 9 of gestation died soon after dosing, while no deaths occurred at doses of 4–15 mg As/kg (Stump et al. 1999). Data on lethality from repeated exposure studies in animals are relatively sparse. Seven of 20 pregnant rabbits died from repeated gavage doses of 1.5 mg As/kg/day as arsenic acid during gestation, while none died at 0.1–0.4 mg As/kg/day (Nemec et al. 1998). Chronic studies observed treatment-related mortality in monkeys exposed to 3 mg As/kg/day as arsenate (Heywood and Sortwell 1979), dogs exposed to 2.4 mg As/kg/day as arsenite or arsenate (Byron et al. 1967), mice exposed to 1 mg As/kg/day as arsenite (Schroeder and Balassa 1967), and rats exposed to 30 mg As/kg/day as lead arsenate (Kroes et al. 1974).

Reliable LOAEL and LD_{50} values for lethality from oral exposure to inorganic arsenicals in each species and duration category are recorded in Table 3-3 and plotted in Figure 3-3.

Organic Arsenicals. No studies were located regarding death in humans after oral exposure to organic arsenicals, but the acute lethality of MMA, DMA, and roxarsone have been investigated in several animal studies. The LD_{50} values for MMA (including MSMA), DMA, and roxarsone are 102–3,184 mg/kg MMA or MSMA (Gur and Nyska 1990; Jaghabir et al. 1988; Kaise et al. 1989), 1,200 mg DMA/kg/day (Kaise et al. 1989), and 14.2–69.5 mg DMA/kg/day (Kerr et al. 1963; NTP 1989b), respectively. The cause of death was not investigated in any of these studies. Intermediate-duration exposure to MMA, DMA, or roxarsone resulted in increased mortality in laboratory animals exposed to 106.9 mg MMA/kg/day (Arnold et al. 2003), 17–190 mg DMA/kg/day (Crown et al. 1987; Murai et al. 1993; Wanibuchi et al. 1996) or 20–64 mg/kg/day roxarsone (Edmonds and Baker 1986; Kerr et al. 1963; NTP 1989b), respectively. Increased mortality was also observed in rats chronically exposed to 72.4 mg MMA/kg/day (Arnold et al. 2003).

3.2.2.2 Systemic Effects

The highest NOAEL values and all reliable LOAEL values for systemic effects from oral exposure in each species and duration category are recorded in Table 3-3 and plotted in Figure 3-3. Similar data for

oral exposure to MMA, DMA, and roxarsone are shown in Tables 3-4, 3-5, and 3-6, and shown in Figures 3-4, 3-5, and 3-6, respectively.

Respiratory Effects.

Inorganic Arsenicals. Serious respiratory effects, including respiratory distress, hemorrhagic bronchitis, and pulmonary edema, have been reported in some cases of acute oral arsenic poisoning at doses of 8 mg As/kg and above (e.g., Civantos et al. 1995; Fincher and Koerker 1987; Levin-Scherz et al. 1987; Moore et al. 1994b; Quatrehomme et al. 1992). These effects may be secondary to injury to the pulmonary vasculature (see Cardiovascular Effects, below). In addition, bronchitis and sequelae (bronchiectasis, bronchopneumonia) have been observed in patients and at autopsy in some chronic poisoning cases (Guha Mazumder et al. 2005; Milton and Rahman 2002; Rosenberg 1974; Tsai et al. 1999; Zaldívar 1974; Zaldívar and Guillier 1977). Bronchopneumonia secondary to arsenic-induced bronchitis was considered to be the cause of death in one young child who died after several years of exposure to an average dose of 0.08 mg As/kg/day (Zaldívar and Guillier 1977). Decrements in lung function, measured as decreased FEV_1, FVC, and FEF_{25-75} have also been reported in subjects exposed to 0.1–0.5 mg As/L in the drinking water and exhibiting skin lesions (von Ehrenstein et al. 2005). In general, however, respiratory effects have not been widely associated with repeated oral ingestion of low arsenic doses. Nevertheless, a few studies have reported minor respiratory symptoms, such as cough, sputum, rhinorrhea, and sore throat, in people with repeated oral exposure to 0.03–0.05 mg As/kg/day (Ahmad et al. 1997; Mizuta et al. 1956).

There are few data regarding respiratory effects in animals following acute oral exposure to inorganic arsenic. An infant Rhesus monkey that died after 7 days of oral exposure to a complex arsenate salt at a dose of 3 mg As/kg/day exhibited bronchopneumonia with extensive pulmonary hemorrhage, edema, and necrosis (Heywood and Sortwell 1979). Two other monkeys in this treatment group survived a 1-year exposure period and had no gross or microscopic pulmonary lesions at sacrifice. Increased relative lung weights were seen in rats exposed to 6.66 mg As/kg/day as sodium arsenite 5 days/week for 12 weeks (Schulz et al. 2002). Chronic oral studies in dogs and rats treated with arsenate or arsenite failed to find respiratory lesions (Byron et al. 1967; Kroes et al. 1974; Schroeder et al. 1968).

One study utilizing gallium arsenide included limited investigation of respiratory function. Respiration rate was significantly decreased in rats following ingestion of a single dose of gallium arsenide at 1,040 mg As/kg, but was unaffected at a dose of 520 mg As/kg (Flora et al. 1997a). Respiration rate was measured 1, 7, and 15 days after dosing, but the decrease was most noticeable after 15 days.

Organic Arsenicals. No respiratory effects were noted after acute human ingestion of 1,714 mg MSMA/kg (Shum et al. 1995). Mice exhibited respiratory arrest after a single oral dose of 1,800 mg MMA/kg (Kaise et al. 1989) or 900 mg DMA/kg (Kaise et al. 1989) and lung ornithine decarboxylase activity was reduced after ingestion of one or two doses of 720 mg DMA/kg (Ahmad et al. 1999a). Localized lung hemorrhage was observed in dogs after a single oral dose of 14.2 mg/kg roxarsone in a capsule (Kerr et al. 1963). No respiratory effects were seen after intermediate or chronic exposure of rats, mice, or dogs exposed to 35 mg MMA/kg/day (Waner and Nyska 1988), 7.8–94 mg DMA/kg/day (Arnold et al. 2006; Crown et al. 1987; Rubin et al. 1989; Zomber et al. 1989), or 4–136 mg/kg/day roxarsone (NTP 1989b).

Cardiovascular Effects.

Inorganic Arsenicals. A number of studies in humans indicate that arsenic ingestion may lead to serious effects on the cardiovascular system. Characteristic effects on the heart from both acute and long-term exposure include altered myocardial depolarization (prolonged QT interval, nonspecific ST segment changes) and cardiac arrhythmias (Cullen et al. 1995; Glazener et al. 1968; Goldsmith and From 1986; Heyman et al. 1956; Little et al. 1990; Mizuta et al. 1956; Moore et al. 1994b; Mumford et al. 2007). A significant dose-related increase in the prevalence of cardiac electrophysiologic abnormalites was observed in residents of Inner Mongolia, China; the incidences of QT prolongation were observed in 3.9, 11.1, and 20.6% of the residents with drinking water levels of <21, 110–300, and 430–690 µg/L, respectively (Mumford et al. 2007). Hypertrophy of the ventricular wall was observed at autopsy after acute exposure to 93 mg of arsenic (Quatrehomme et al. 1992). Long-term, low-level exposures may also lead to damage to the vascular system. The most dramatic example of this is "Blackfoot Disease," a condition that is endemic in an area of Taiwan where average drinking water levels of arsenic range from 0.17 to 0.80 ppm (Tseng 1977), corresponding to doses of about 0.014–0.065 mg As/kg/day (IRIS 2007). The disease is characterized by a progressive loss of circulation in the hands and feet, leading ultimately to necrosis and gangrene (Chen et al. 1988b; Ch'i and Blackwell 1968; Tseng 1977, 1989; Tseng et al. 1968, 1995, 1996). Several researchers have presented evidence that other factors besides arsenic (e.g., other water contaminants, dietary deficits) may play a role in the etiology of this disease (Ko 1986; Lu et al. 1990; Yu et al. 1984). While this may be true, the clear association between the occurrence of Blackfoot Disease and the intake of elevated arsenic levels indicates that arsenic is at least a contributing factor. The results of a recent study suggested that individuals with a lower capacity to methylate

inorganic arsenic to DMA have a higher risk of developing peripheral vascular disease in the Blackfoot Disease-hyperendemic area in Taiwan (Tseng et al. 2005).

Arsenic exposure in Taiwan has also been associated with an increased incidence of cerebrovascular and microvascular diseases (Chiou et al. 1997; Wang et al. 2002, 2003) and ischemic heart disease (Chang et al. 2004; Chen et al. 1996; Hsueh et al. 1998b; Tsai et al. 1999; Tseng et al. 2003). Moreover, effects of arsenic on the vascular system have also been reported in a number of other populations. For example, hypertension, defined as a systolic blood pressure of ≥140 mm Hg in combination with a diastolic blood pressure of ≥90 mm Hg, was associated with estimated lifetime doses of approximately 0.055 mg As/kg/day (0.25 mg/L in water) in a study of people in Bangladesh (Rahman et al. 1999); no significant association was found with estimated doses of 0.018 mg As/kg/day (0.75 mg/L in water). Wang et al. (2003) found an increased incidence of microvascular and macrovascular disease among subjects in Taiwan living in an arseniasis-endemic area in which the water of artesian wells had arsenic concentrations >0.35 mg/L (estimated doses of >0.03 mg As/kg/day). An additional study of Taiwanese subjects reported a significant increase in incidence of hypertension associated with concentrations of arsenic in the water >0.7 mg/L (estimated doses of >0.06 mg As/kg/day) (Chen et al. 1995). Studies in Chile indicate that ingestion of 0.6–0.8 ppm arsenic in drinking water (corresponding to doses of 0.02–0.06 mg As/kg/day, depending on age) increases the incidence of Raynaud's disease and of cyanosis of fingers and toes (Borgoño and Greiber 1972; Zaldívar 1974, 1977; Zaldívar and Guillier 1977). Autopsy of five children from this region who died of apparent arsenic toxicity showed a marked thickening of small and medium sized arteries in tissues throughout the body, especially the heart (Rosenberg 1974). In addition, cardiac failure, arterial hypotension, myocardial necrosis, and thrombosis have been observed in children who died from chronic arsenic ingestion (Zaldívar 1974), as well as adults chronically exposed to arsenic (Dueñas et al. 1998). Likewise, thickening and vascular occlusion of blood vessels were noted in German vintners exposed to arsenical pesticides in wine and in adults who drank arsenic-contaminated drinking water (Roth 1957; Zaldívar and Guillier 1977). A survey of Wisconsin residents using private wells for their drinking water found that residents exposed for at least 20 years to water concentrations of >10 µg As/L had increased incidences of cardiac bypass surgery, high blood pressure, and circulatory problems as compared with residents exposed to lower arsenic concentrations (Zierold et al. 2004). Similarly, Lewis et al. (1999) reported increased mortality from hypertensive heart disease in both men and women among a cohort exposed to arsenic in their drinking water in Utah, as compared with the general population of Utah. Limitations in the study included lack of evaluation of smoking as a confounder and of other dietary sources of arsenic, and the lack of a dose-response for hypertensive heart disease. Another ecological study (Engel and Smith 1994) found significant increases in deaths from

arteriosclerosis, aortic aneurysm, and all other diseases of the arteries, arterioles, and capillaries among U.S. residents with arsenic drinking waters of >20 µg/L; the increase in deaths from congenital anomalies of the heart and other anomalies of the circulatory system also observed in this subpopulation limits the interpretation of the findings.

Similar alterations in vascular reactivity have been noted in rats given repeated oral doses of arsenic trioxide (11 mg As/kg/day) for several weeks (Bekemeier and Hirschelmann 1989), although no histological effects could be detected in the hearts of rats or dogs exposed to up to 30 mg As/kg/day as arsenate or arsenite for 2 years (Byron et al. 1967; Kroes et al. 1974; Schroeder et al. 1968). Acute exposure of rats to gallium arsenide at a dose of 1,040 mg As/kg resulted in an increase in blood pressure and heart rate, while 520 mg As/kg had no effect (Flora et al. 1997a). Guinea pigs exposed to arsenic trioxide for 1 day (0, 7.6, 22.7, or 37.9 mg As/kg) or 8 days (0 or 3.8 mg As/kg/day) showed prolongation of the cardiac QT interval and action potential duration (Chiang et al. 2002).

Organic Arsenicals. No adverse cardiovascular effects were noted after acute human ingestion of 1,714 mg MSMA/kg (Shum et al. 1995). However, sinus tachycardia was noted after acute ingestion of 73 mg DMA/kg (as dimethyl arsenic acid and dimethyl arsenate) (Lee et al. 1995). No cardiovascular effects were seen after intermediate or chronic exposure of laboratory animals to 35–67.1 mg MMA/kg/day (Arnold et al. 2003; Waner and Nyska 1988), 7.8–94 mg DMA/kg/day (Arnold et al. 2006; Crown et al. 1987; Rubin et al. 1989; Zomber et al. 1989), or 4–136 mg/kg/day roxarsone (NTP 1989b).

Gastrointestinal Effects.

Inorganic Arsenicals. Clinical signs of gastrointestinal irritation, including nausea, vomiting, diarrhea, and abdominal pain, are observed in essentially all cases of short-term high-dose exposures to inorganic arsenic (e.g., Armstrong et al. 1984; Bartolome et al. 1999; Campbell and Alvarez 1989; Chakraborti et al. 2003a; Cullen et al. 1995; Fincher and Koerker 1987; Goebel et al. 1990; Kingston et al. 1993; Levin-Scherz et al. 1987; Lugo et al. 1969; Moore et al. 1994b; Muzi et al. 2001; Uede and Furukawa 2003; Vantroyen et al. 2004). Similar signs are also frequently observed in groups or individuals with longer-term, lower-dose exposures (e.g., Borgoño and Greiber 1972; Cebrián et al. 1983; Franzblau and Lilis 1989; Guha Mazumder et al. 1988, 1998a; Haupert et al. 1996; Holland 1904; Huang et al. 1985; Mizuta et al. 1956; Nagai et al. 1956; Silver and Wainman 1952; Wagner et al. 1979; Zaldívar 1974), but effects are usually not detectable at exposure levels below about 0.01 mg As/kg/day (Harrington et al. 1978; Valentine et al. 1985). These symptoms generally decline within a short time after exposure ceases.

Gastrointestinal irritation symptoms form the basis (in part) for the acute oral MRL of 0.005 mg/kg/day for inorganic arsenic, as described in footnote b in Table 3-3. More severe symptoms (hematemesis, hemoperitoneum, gastrointestinal hemorrhage, and necrosis) have been reported in some cases with acute exposure to 8 mg As/kg or more (Civantos et al. 1995; Fincher and Koerker 1987; Levin-Scherz et al. 1987; Quatrehomme et al. 1992), and also in some people with long-term ingestion of 0.03–0.05 mg As/kg/day as a medicinal preparation (Lander et al. 1975; Morris et al. 1974).

Clinical signs of gastrointestinal irritation were observed in monkeys and rats given repeated oral doses of arsenic (6 and 11 mg As/kg/day, respectively) for 2 weeks (Bekemeier and Hirschelmann 1989; Heywood and Sortwell 1979). Hemorrhagic gastrointestinal lesions have also been reported in animal studies. A monkey that died after repeated oral treatment with 6 mg As/kg/day for approximately 1 month was found to have acute inflammation and hemorrhage of the small intestine upon necropsy (Heywood and Sortwell 1979). This lesion was not found in other monkeys that died in this study, or in the survivors. Two pregnant mice that died after repeated gavage treatment with 24 mg As/kg/day as arsenic acid had hemorrhagic lesions in the stomach (Nemec et al. 1998). Gross gastrointestinal lesions (stomach adhesions, eroded luminal epithelium in the stomach) were seen frequently in rats treated by gavage with 8 mg As/kg/day as arsenic trioxide starting before mating and continuing through the end of gestation (Holson et al. 2000). The lesions were not found in rats treated with 4 mg As/kg/day in this study. No histological evidence of gastrointestinal injury was detected in rats exposed to arsenate or arsenite in the feed for 2 years at doses up to 30 mg As/kg/day, but dogs fed a diet containing 2.4 mg As/kg/day as arsenite for 2 years had some bleeding in the gut (Byron et al. 1967; Kroes et al. 1974).

Organic Arsenicals. Vomiting was noted after ingestion of 793 mg/kg arsenic (as monosodium methanearsenate) in a suicide attempt (Shum et al. 1995). Ingestion of 78 mg DMA/kg (as dimethyl arsenic acid and dimethyl arsenate) induced vomiting, abdominal pain, hyperactive bowel, and diarrhea (Lee et al. 1995).

The gastrointestinal tract appears to be the critical target of toxicity following oral exposure to MMA. Diarrhea/loose feces has been reported in mice and rabbits following a single gavage dose of 2,200 mg MMA/kg or 60 mg MSMA/kg, respectively (Jaghabir et al. 1988; Kaise et al. 1989), pregnant rabbits administered 12 mg MMA/kg/day via gavage (Irvine et al. 2006), rats exposed to 30.2 mg MMA/kg/day in the diet during the first year of a 2-year study (Arnold et al. 2003), dogs administered 2 mg MMA/kg/day via capsule for 52 weeks (Waner and Nyska 1988), rats fed diets containing 25.7 mg MMA/kg/day for 2 years (Arnold et al. 2003), and mice exposed to 67.1 mg MMA/kg/day in the diet for

2 years (Arnold et al. 2003). However, the increased incidence of diarrhea is not always accompanied by macroscopic or histological alterations in the gastrointestinal tissues. For example, in the 2-year rat study (Arnold et al. 2003; incidence data reported in Crown et al. 1990), an increased incidence of diarrhea was observed at 25.7 mg MMA/kg/day; macroscopic or histological alterations were observed in some animals, but the incidence was similar to controls. At the next highest dose level (72.4 mg MMA/kg/day), thickened wall and edema and hemorrhagic, necrotic, ulcerated, or perforated mucosa were observed in the large intestine and significant increases in the incidence of squamous metaplasia of the epithelial columnar absorptive cells were found in the cecum, colon, and rectum. Squamous metaplasia was also observed in the cecum and colon of mice chronically exposed to 67.1 mg MMA/kg/day (Arnold et al. 2003; incidence data reported in Gur et al. 1991).

There are some reports of gastrointestinal effects in rats and dogs exposed to DMA; however, the LOAELs for these effects are higher than the LOAELs for MMA and most rodent studies do not report effects at nonlethal doses. Diarrhea with congestion and hemorrhagic gastrointestinal contents were observed in rats exposed to a lethal dose of 190 mg DMA/kg/day in the diet for 4 weeks (Crown et al. 1987) and diarrhea and vomiting were reported in dogs administered 16 mg DMA/kg/day via capsule 6 days/week (Zomber et al. 1989). No gastrointestinal effects were observed in rats or mice chronically exposed to 7.8 or 94 mg DMA/kg/day, respectively (Arnold et al. 2006).

Vomiting and gastrointestinal hemorrhage were observed in dogs after a single capsulized dose of 50 mg/kg roxarsone (Kerr et al. 1963), although slightly higher doses administered for 13 weeks to rats and mice had no effect (NTP 1989b). No gastrointestinal effects were seen after chronic exposure of rats (4 mg/kg/day) or mice (43 mg/kg/day) to roxarsone (NTP 1989b).

Hematological Effects.

Inorganic Arsenicals. Anemia and leukopenia are common effects of arsenic poisoning in humans, and have been reported following acute (Armstrong et al. 1984; Goldsmith and From 1986; Mizuta et al. 1956; Muzi et al. 2001; Westhoff et al. 1975), intermediate (Franzblau and Lilis 1989; Heyman et al. 1956; Nagai et al. 1956; Wagner et al. 1979), and chronic oral exposures (Chakraborti et al. 2003a; Glazener et al. 1968; Guha Mazumder et al. 1988; Hopenhayn et al. 2006; Kyle and Pease 1965; Tay and Seah 1975) at doses of 0.002 mg As/kg/day or more. These effects may be due to both a direct cytotoxic or hemolytic effect on the blood cells (Armstrong et al. 1984; Fincher and Koerker 1987; Goldsmith and From 1986; Kyle and Pease 1965; Lerman et al. 1980) and a suppression of erythropoiesis (Kyle and

Pease 1965; Lerman et al. 1980). However, hematological effects are not observed in all cases of arsenic exposure (EPA 1981b; Harrington et al. 1978; Huang et al. 1985; Silver and Wainman 1952) or even all acute poisoning cases (Cullen et al. 1995; Moore et al. 1994b).

In an acute animal study, Tice et al. (1997) found that there was a decrease in polychromatic erythrocytes in the bone marrow of mice treated with 6 mg As/kg/day for 1 or 4 days. There was no effect at 3 mg As/kg/day. Long-term studies found mild anemia in dogs fed arsenite or arsenate for 2 years at 2.4 mg As/kg/day, but no hematological effect in dogs fed 1 mg As/kg/day for 2 years or 1.9 mg As/kg/day for 26 weeks (Byron et al. 1967; Neiger and Osweiler 1989). Chronic rat studies found little or no evidence of anemia at doses up to 30 mg As/kg/day, even with co-exposure to lead (Byron et al. 1967; Kroes et al. 1974). No hematological effects were found in monkeys exposed to arsenic doses of 3–6 mg As/kg/day for 1 year (Heywood and Sortwell 1979).

Rats exposed to arsenate for 6 weeks had decreased activities of several enzymes involved in heme synthesis, but data were not provided on whether this resulted in anemia (Woods and Fowler 1977, 1978). Exposure of rats to ≥5 ppm of arsenic (0.30 mg As/kg/day as sodium arsenite) in the drinking water for 4 weeks resulted in increased platelet aggregation, while 10 or 25 ppm (0.60 or 1.5 mg As/kg/day) was associated with increased P-selectin-positive cells and decreased occlusion time (Lee et al. 2002), representing a change in platelet function. Similarly, exposure of rats or guinea pigs to 10 or 25 ppm of arsenic as arsenite (approximate doses of 0, 0.92, or 2.3 mg As/kg/day for rats and 0, 0.69, or 1.7 mg As/kg/day for guinea pigs) in the drinking water for 16 weeks (Kannan et al. 2001) resulted in decreases in erythrocyte and leukocyte numbers (rats and guinea pigs), increased blood mean corpuscular volume and corpuscular hemoglobin mass (guinea pigs only), and decreased mean corpuscular hemoglobin concentration (rats only). Gallium arsenide also disrupts heme synthesis in rats, although the evidence suggests that this effect is due primarily to the gallium moiety (Flora et al. 1997a).

Organic Arsenicals. No adverse hematological effects were noted in a man who ingested 78 mg/kg as dimethyl arsenic acid and dimethyl arsenate (Lee et al. 1995). No hematological effects were observed in rats exposed to 8.4 or 72.4 mg MMA/kg/day for 2 years (Arnold et al. 2003; Shen et al. 2003) or dogs administered 35 mg MMA/kg/day for 52 weeks (Waner and Nyska 1988); additionally, no alterations in total or differential leukocyte levels were observed in mice exposed to 67.1 mg MMA/kg/day for 2 years (Arnold et al. 2003). Although some studies have reported hematological alterations following oral exposure to DMA, this is not a consistent finding. Observed alterations include decreased mean corpuscular hemoglobin concentration in rats exposed to 2.3 mg DMA/kg/day for 10 weeks (Rubin et al.

1989), decreased hemoglobin and erythrocyte levels in rats exposed to 4.5 mg DMA/kg/day for 13 weeks (Crown et al. 1987), decreased erythrocyte levels and increased leukocyte levels in dogs administered capsules containing 40 mg DMA/kg/day for 52 weeks (Zomber et al. 1989), and decreased lymphocyte and increased monocyte levels were observed in mice chronically exposed to 94 mg DMA/kg/day (Arnold et al. 2006). No hematological alterations have been observed in rats exposed to 7.8 mg DMA/kg/day for 2 years (Arnold et al. 2006). Similarly, no hematological effects were observed in rats (Kerr et al. 1963; NTP 1989b), mice (NTP 1989b), or dogs (Prier et al. 1963) exposed to 20–32, 68, or 5 mg/kg/day roxarsone, respectively, for intermediate or chronic durations

Musculoskeletal Effects.

Inorganic Arsenicals. No studies were located regarding musculoskeletal effects in humans or animals after oral exposure to inorganic arsenicals.

Organic Arsenicals. No studies were located regarding musculoskeletal effects in humans after oral exposure to organic arsenicals. No musculoskeletal effects were seen after intermediate or chronic exposure of rats and mice to MMA (Arnold et al. 2003), DMA (Arnold et al. 2006), or roxarsone (NTP 1989b).

Hepatic Effects.

Inorganic Arsenicals. A number of studies in humans exposed to inorganic arsenic by the oral route have noted signs or symptoms of hepatic injury. Clinical examination often reveals that the liver is swollen and tender (Chakraborty and Saha 1987; Franklin et al. 1950; Guha Mazumder et al. 1988, 1998a; Liu et al. 2002; Mizuta et al. 1956; Silver and Wainman 1952; Wade and Frazer 1953; Zaldívar 1974), and analysis of blood sometimes shows elevated levels of hepatic enzymes (Armstrong et al. 1984; Franzblau and Lilis 1989; Guha Mazumder 2005; Hernández-Zavala et al. 1998). These effects are most often observed after repeated exposure to doses of 0.01–0.1 mg As/kg/day (Chakraborty and Saha 1987; Franklin et al. 1950; Franzblau and Lilis 1989; Guha Mazumder et al. 1988; Mizuta et al. 1956; Silver and Wainman 1952; Wade and Frazer 1953), although doses as low as 0.006 mg As/kg/day have been reported to have an effect following chronic exposure (Hernández-Zavala et al. 1998). Hepatic effects have also been reported in acute bolus poisoning cases at doses of 2 mg As/kg/day or more (Hantson et al. 1996; Kamijo et al. 1998; Levin-Scherz et al. 1987; Quatrehomme et al. 1992; Vantroyen et al. 2004), although acute exposure to 19 mg As/kg did not cause hepatic effects in an infant (Cullen et al. 1995).

Histological examination of the livers of persons chronically exposed to similar doses has revealed a consistent finding of portal tract fibrosis (Guha Mazumder 2005; Guha Mazumder et al. 1988; Morris et al. 1974; Piontek et al. 1989; Szuler et al. 1979), leading in some cases to portal hypertension and bleeding from esophageal varices (Szuler et al. 1979); cirrhosis has also been reported at an increased frequency in arsenic-exposed individuals (Tsai et al. 1999). Several researchers consider that these hepatic effects are secondary to damage to the hepatic blood vessels (Morris et al. 1974; Rosenberg 1974), but this is not directly established.

Acute exposure of monkeys to 6 mg As/kg/day resulted in vacuolization of the hepatocytes (Heywood and Sortwell 1979). Studies in dogs or mice have not detected clinically significant hepatic injury following exposure to either arsenite or arsenate (Byron et al. 1967; Fowler and Woods 1979; Kerkvliet et al. 1980; Neiger and Osweiler 1989; Schroeder and Balassa 1967), although enlargement of the common bile duct was noted in rats fed either arsenate or arsenite in the diet for 2 years (Byron et al. 1967; Kroes et al. 1974) and lipid vacuolation and fibrosis were seen in the livers of rats exposed to 12 mg As/kg/day as arsenate in the drinking water for 6 weeks (Fowler et al. 1977). Similarly, fatty changes and inflammatory cell infiltration were seen in the livers of both normal and metallothionein-null mice exposed to 5.6 mg arsenic/kg/day in the drinking water for 48 weeks (Liu et al. 2000). Increases in liver zinc and copper concentrations were noted in rats receiving a single oral dose of 10 mg As/kg as sodium arsenite (Flora and Tripathi 1998) and hepatic levels of malondialdehyde were increased and glutathione levels were decreased in livers of rats receiving 200 mg As/kg as GaAs (Flora et al. 1998). An increase in indices of peroxidation was reported in rats dosed with approximately 0.02 mg As/kg/day for 60 days from drinking water containing 2.5 mg sodium arsenite/L (Bashir et al. 2006); absolute liver weight was also increased at this dose level. Elevated levels of serum aspartate aminotransferase (AST) were observed in rats administered a single oral dose of 100 mg As/kg as GaAs (Flora et al. 1998). Exposure of guinea pigs to 0.69 or 1.7 mg As/kg/day in the drinking water for 16 weeks, but not in rats exposed to 0.92 or 2.3 mg As/kg/day, resulted in increases in delta-aminolevulinic acid synthetase (ALAS) levels (Kannan et al. 2001). Exposure of BALB/C mice to 0.7 mg arsenic/kg/day in the drinking water for 15 months resulted in increased liver weights, changes in liver enzymes (glutathione S-transferase, glutathione reductase, catalase, glucose-6-phosphate dehydrogenase, glutathione peroxidase), fatty liver, and fibrosis (Santra et al. 2000).

Organic Arsenicals. No adverse hepatic effects were noted after ingestion of 1,714 mg/kg MSMA or 78 mg DMA/kg (as dimethyl arsenic acid and dimethyl arsenate) in a suicide attempt (Lee et al. 1995; Shum et al. 1995). No other studies of the hepatic effects of organic arsenicals in humans were located.

Histological examination of livers from rabbits given repeated oral doses of MMA showed diffuse inflammation and hepatocellular degeneration (Jaghabir et al. 1989), but the lesions were not severe. Male rats exposed to a time-weighted average (TWA) dose of 72.4 mg MMA/kg/day for 104 weeks showed a decrease in absolute liver weight, while females exposed to 98.5 mg MMA/kg/day showed histiocytic proliferation of the liver (Arnold et al. 2003); however, these effects were probably due to a decrease in body weight and secondary complications of perforation and ulceration of the gastrointestinal effect, respectively. Shen et al. (2003) reported increases in and the number of GST-P-positive foci in the livers of rats exposed to average concentrations of 8.4 mg MMA/kg/day in the diet for 104 weeks. No effects were observed in rats exposed to DMA (Siewicki 1981), but mice exposed to one or two oral doses of 720 mg DMA/kg had decreased liver glutathione and cytochrome P-450 content and serum ornithine decarboxylase activity (Ahmad et al. 1999a). Generalized icterus was reported in dogs after acute exposure to roxarsone (Kerr et al. 1963). Some small fluctuations in liver weight have been noted in rats and mice after intermediate oral exposure to roxarsone, but the toxicological significance of this is not clear and is not observed after chronic exposure of rats and mice to lower doses (NTP 1989b).

Renal Effects.

Inorganic Arsenicals. Most case studies of acute and chronic arsenic toxicity do not report clinical signs of significant renal injury, even when other systems are severely impaired (e.g., Cullen et al. 1995; Franzblau and Lilis 1989; Jenkins 1966; Kersjes et al. 1987; Mizuta et al. 1956; Silver and Wainman 1952). In some cases, elevated serum levels of creatinine or bilirubin have been noted (Armstrong et al. 1984; Levin-Scherz et al. 1987; Moore et al. 1994b), and mild proteinuria may occur (Armstrong et al. 1984; Glazener et al. 1968; Tay and Seah 1975). Acute renal failure in some bolus poisoning episodes (e.g., Fincher and Koerker 1987; Goebel et al. 1990; Levin-Scherz et al. 1987; Lugo et al. 1969; Moore et al. 1994b) is probably a result of fluid imbalances or vascular injury (Rosenberg 1974; Zaldívar 1974). Glomerular congestion has been observed after an acute exposure to high doses (Quatrehomme et al. 1992).

Studies in animals also indicate that the kidney is not a major target organ for inorganic arsenic (Byron et al. 1967; Schroeder and Balassa 1967; Woods and Southern 1989), although some effects have been reported at high exposure levels. Mild histological changes in the renal tubules of monkeys exposed to arsenate for 2 weeks were noted by Heywood and Sortwell (1979), and some mild alterations in renal mitochondria in rats exposed to arsenate for 6 weeks were noted by Brown et al. (1976). Mild proteinuria

(Flora et al. 1998) and an increase in kidney zinc concentration (Flora and Tripathi 1998) have also been noted in rats exposed orally to a single dose of 100 mg As/kg as GaAs or 10 mg As/kg as sodium arsenite, respectively. These data suggest that the kidney is relatively less sensitive to arsenic than most other organ systems, and renal effects are unlikely to be of concern except secondary to fluid imbalances or cardiovascular injury.

Organic Arsenicals. No adverse renal effects were noted after ingestion of 1,714 mg MSMA/kg in a suicide attempt (Shum et al. 1995). Animal studies have reported renal and urinary bladder effects following oral exposure to organic arsenicals; the available data suggest that the urinary system is a more sensitive target for DMA, than for MMA or roxarsone. A decrease in urine volume was observed in rabbits following a single gavage dose of 30 mg MSMA/kg/day (Jaghabir et al. 1988) and a decrease in urine volume (35 mg MMA/kg/day) and an increase in urine specific gravity (8 mg MMA/kg/day) were observed in dogs administered MMA via capsule for 52 weeks (Waner and Nyska 1988). However, these effects may be indicative of dehydration due to diarrhea rather than a direct effect on the kidney. In a 2-year study in rats (Arnold et al. 2003), an increase in the severity of progressive glomerulonephropathy was observed in females at 33.9 mg MMA/kg/day. Hydronephrosis, pyelonephritis, cystitis, and decreases in urine volume and pH were also observed 72.4 mg MMA/kg/day; however, the investigators noted that these lesions probably resulted from urinary tract obstruction, which was secondary to peritonitis caused by gastrointestinal tract ulcerations. An increased incidence of progressive glomerulonephropathy was also observed in male mice exposed to ≥6.0 mg MMA/kg/day in the diet for 2 years (Arnold et al. 2003; incidence data reported in Gur et al. 1991); the investigators (Gur et al. 1991) noted that the kidney lesions were consistent with the normal spectrum of spontaneous lesions and that there were no differences in character or severity of the lesions between the different groups.

Exposure to DMA has resulted in kidney effects in rats and mice exposed to at least 3.1 or 37 mg DMA/kg/day, respectively; no renal effects were observed in dogs exposed to doses as high as 40 mg As/kg/day for 52 weeks (Zomber et al. 1989). In rats, the renal damage is characterized by increased urine volume and pH, decreased urine osmolarity and electrolyte (sodium, potassium, chlorine) levels, increased urinary calcium levels, and increased organ weight, nephrocalcinosis, and necrosis in the renal papillae and/or cortex; an increase in water consumption is also typically observed. The LOAELs for these effects are 5–57 mg DMA/kg/day in intermediate-duration studies (Arnold et al. 1999; Crown et al. 1987; Murai et al. 1993) and 3.1 mg DMA/kg/day in a chronic-duration study (Arnold et al. 2006). Another study did not find renal effects in rats exposed to 16.5 mg DMA/kg/day (Rubin et al. 1989). This study involved exposure to Sprague-Dawley rats compared to Fischer 344 rats used in the studies with

positive results; it is not known if this reflects a difference in strain sensitivity. In mice, progressive glomerulonephropathy was observed at 37 mg DMA/kg/day and nephrocalcinosis was observed at 94 mg DMA/kg/day (Arnold et al. 2006).

Increased kidney weights and minimal tubular epithelial cell degeneration, tubular casts, and focal mineralization were observed in rats exposed to 32 mg/kg/day roxarsone for 13 weeks (NTP 1989b). No adverse effects were observed in rats at doses as high as 20 mg/kg/day (Kerr et al. 1963; NTP 1989b) for 13 weeks or 10 mg/kg/day for 2 years (NTP 1989b; Prier et al. 1963). No adverse renal effects have been observed in mice exposed to roxarsone doses as high as 136 mg/kg/day (NTP 1989b) or 43 mg/kg/day (NTP 1989b; Prier et al. 1963) for intermediate or chronic durations, respectively, or in dogs exposed to 5 mg/kg/day for a chronic duration (Prier et al. 1963).

Damage to the urinary bladder has been observed in several studies in which rats were exposed to DMA. The observed effects include altered bladder cell surface characteristics in rats exposed to 11 mg DMA/kg/day in the diet for 2 weeks (Cohen et al. 2001), increased bladder weight and regenerative proliferation (measured as an increase in BrdU labeling) in bladder epithelium at 5 mg DMA/kg/day for 10 weeks (Arnold et al. 1999), necrosis of bladder epithelium at 10 mg DMA/kg/day for 10 weeks (Arnold et al. 1999), nodular or papillar hyperplasia at 3.4 mg DMA/kg/day for 2 years (Wei et al. 2002), and urothelial vacuolar degeneration and hyperplasia of urothelial cells at 3.1 mg DMA/kg/day for 2 years (Arnold et al. 2006). Vacuolization of the urothelium in the urinary bladder have also been observed in mice exposed to 7.8 mg DMA/kg/day in the diet for 2 years (Arnold et al. 2006). Inconsistent results were found for MMA. Hyperplasia was observed in the bladders of rats exposed to 1 mg As/kg/day as MMA in drinking water for 2 years (Shen et al. 2003), but bladder effects were not observed in another 2-year study (Arnold et al. 2003) in which rats were exposed to doses as high as 34.8 mg As/kg/day as MMA in the diet. No urinary bladder effects were found in rats and mice exposed to 64 or 136 mg/kg/day roxarsone for 13 weeks (NTP 1989b) or 4 or 43 mg/kg/day roxarsone for 2 years (NTP 1989b).

Endocrine Effects.

Inorganic Arsenicals. Very little has been written about the effects of oral exposure to arsenic on endocrine glands. In a report of the autopsies of five children who died in Chile after chronic exposure to arsenic in the drinking water, arterial thickening in the pancreas was noted (Rosenberg 1974). An association has been demonstrated between exposure to arsenic in drinking water and an increased

incidence of diabetes mellitus (Lai et al. 1994; Rahman et al. 1998; Tsai et al. 1999; Tseng et al. 2000; Wang et al. 2003), although dose-response relationships are not available.

Exposure of rats to 2.3 mg As/kg/day as arsenic trioxide for 30 days resulted in reductions in the number of islet cells in the pancreas, as well as significant reductions in pancreatic superoxide dismutase (SOD) and catalase enzyme levels and increases in the production of nitric oxide and malondialdehyde (Mukherjee et al. 2004).

Organic Arsenicals. No studies of effects of organic arsenic compounds on endocrine glands in humans were found. Hypertrophy of thyroid epithelium was observed in rats exposed to 33.9 mg MMA/kg/day in the diet for 2 years (Arnold et al. 2003), 4.0 mg DMA/kg/day in the diet for 13 weeks (Crown et al. 1987), 16.5 mg DMA/kg/day in the diet for at least 10 weeks (Rubin et al. 1989), and 7.8 mg DMA/kg/day in the diet for 2 years (Arnold et al. 2006). No other biologically significant effects were observed in other endocrine tissues following exposure to MMA or DMA. No adverse effects were seen in the adrenal or pituitary glands, thyroid, or pancreas after intermediate or chronic exposure of rats (20–64 or 4 mg/kg/day, respectively) and mice (136 or 43 mg/kg/day, respectively) to roxarsone (NTP 1989b).

Dermal Effects.

Inorganic Arsenicals. One of the most common and characteristic effects of arsenic ingestion is a pattern of skin changes that include generalized hyperkeratosis and formation of hyperkeratotic warts or corns on the palms and soles, along with areas of hyperpigmentation interspersed with small areas of hypopigmentation on the face, neck, and back. These and other dermal effects have been noted in a large majority of human studies involving repeated oral exposure (e.g., Ahmad et al. 1997, 1999b; Ahsan et al. 2000; Bickley and Papa 1989; Borgoño and Greiber 1972; Borgoño et al. 1980; Cebrián et al. 1983; Chakraborti et al. 2003a, 2003b; Chakraborty and Saha 1987; Foy et al. 1992; Franklin et al. 1950; Franzblau and Lilis 1989; Guha Mazumder et al. 1988, 1998a, 1998b, 1998c; Guo et al. 2001a; Haupert et al. 1996; Huang et al. 1985; Lander et al. 1975; Liu et al. 2002; Lüchtrath 1983; Milton et al. 2004; Mizuta et al. 1956; Morris et al. 1974; Nagai et al. 1956; Piontek et al. 1989; Rosenberg 1974; Saha and Poddar 1986; Silver and Wainman 1952; Szuler et al. 1979; Tay and Seah 1975; Tseng et al. 1968; Wade and Frazer 1953; Wagner et al. 1979; Wong et al. 1998a, 1998b; Zaldívar 1974, 1977). In cases of low-level chronic exposure (usually from water), these skin lesions appear to be the most sensitive indication of effect, so this end point is considered to be the most appropriate basis for establishing a chronic oral MRL. This is supported by the finding that other effects (hepatic injury, vascular disease, neurological

effects) also appear to have similar thresholds. As shown in Table 3-3 and Figure 3-3, numerous studies in humans have reported dermal effects at chronic dose levels generally ranging from about 0.01 to 0.1 mg As/kg/day (Ahmad et al. 1997; Bickley and Papa 1989; Borgoño and Greiber 1972; Borgoño et al. 1980; Cebrián et al. 1983; Chakraborty and Saha 1987; Foy et al. 1992; Franklin et al. 1950; Guha Mazumder et al. 1988; Huang et al. 1985; Lüchtrath 1983; Piontek et al. 1989; Silver and Wainman 1952; Tseng et al. 1968; Zaldívar 1974, 1977). However, in a study with detailed exposure assessment, all confirmed cases of skin lesions ingested water containing >100 µg/L arsenic (approximately 0.0037 mg As/kg/day) and the lowest known peak arsenic concentration ingested by a case was 0.115 µg/L (approximately 0.0043 mg As/kg/day) (Haque et al. 2003). Another large study reported increased incidence of skin lesions associated with estimated doses of 0.0012 mg As/kg/day (0.023 mg As/L drinking water) (Ahsan et al. 2006). Several epidemiological studies of moderately sized populations (20–200 people) exposed to arsenic through drinking water have detected no dermal or other effects at average chronic doses of 0.0004–0.01 mg As/kg/day (Cebrián et al. 1983; EPA 1981b; Guha Mazumder et al. 1988; Harrington et al. 1978; Valentine et al. 1985), and one very large study detected no effects in any person at an average total daily intake (from water plus food) of 0.0008 mg As/kg/day (Tseng et al. 1968). This value has been used to calculate a chronic oral MRL for inorganic arsenic of 0.0003 mg/kg/day, as described in footnote c in Table 3-3.

Another prominent dermal effect associated with chronic ingestion of inorganic arsenic is skin cancer. As discussed in greater detail in Section 3.2.2.7 (below), some of these skin cancers may evolve from the hyperkeratotic corns or warts, while the areas of altered pigmentation are not considered to be precancerous (EPA 1988d).

Dermal lesions similar to those observed in humans have not been noted in oral exposure studies in monkeys (Heywood and Sortwell 1979), dogs (Byron et al. 1967), or rodents (Schroeder et al. 1968). However, a hyperplastic response to oral arsenic exposure was reported in arsenic-exposed mice (Rossman et al. 2004).

Organic Arsenicals. No studies were located regarding dermal effects in humans after oral exposure to organic arsenicals. No gross or histological skin alterations were observed in rats or mice following intermediate- or chronic-duration exposure to MMA (Arnold et al. 2003; as reported in Crown et al. 1990; Gur et al. 1991), DMA (Arnold et al. 2006; as reported in Gur et al. 1989a, 1989b), or roxarsone (NTP 1989b)

Ocular Effects.

Inorganic Arsenicals. Periorbital swelling was reported in people drinking contaminated well water at an approximate dose of 0.2 mg As/kg for 1 week (Armstrong et al. 1984). Facial edema, generally involving the eyelids, was a prominent feature of arsenic poisoning among 220 cases associated with an episode of arsenic contamination of soy sauce in Japan (Mizuta et al. 1956). Exposure was to an estimated dose of 0.05 mg/kg/day and lasted for up to 2–3 weeks. The edema developed soon after the initial exposure and then subsided. This effect forms the basis (in part) for the acute oral MRL of 0.005 mg/kg/day for inorganic arsenic, as described in footnote b in Table 3-3. Nemec et al. (1998) noted the appearance of dried red material around the eyes of mice receiving daily oral doses of 24 mg As/kg as arsenic acid for 10 days during gestation.

Organic Arsenicals. No studies were located regarding ocular effects in humans or animals after oral exposure to organic arsenicals. No gross or histological alterations in the eye were observed in rats or mice following intermediate- or chronic-duration exposure to MMA (Arnold et al. 2003; as reported in Crown et al. 1990; Gur et al. 1991), DMA (Arnold et al. 2006; as reported in Gur et al. 1989a, 1989b), or roxarsone (NTP 1989b).

Body Weight Effects.

Inorganic Arsenicals. A 41-year old woman exposed to arsenic in the drinking water for 4 months at an approximate dose of 0.06 mg As/kg/day reported losing 40 pounds (18 kg) of body weight before seeking treatment (Wagner et al. 1979). Weight loss was also among the effects observed in a series of 475 chronic arsenism patients hospitalized in Antofagasto, Chile after receiving approximate doses of 0.02 mg As/kg/day in the drinking water for an unspecified number of years (Zaldívar 1974).

Reductions in body weight gain are commonly seen in animal studies of ingested arsenic. In pregnant rats, body weight gain was reduced by gavage treatment with 23 mg As/kg/day as arsenic trioxide on day 9 of gestation (NOAEL=15 mg As/kg/day, Stump et al. 1999), and by repeated gavage treatment with 8 mg As/kg/day as arsenic trioxide from 2 weeks prior to mating through gestation (NOAEL=4 mg As/kg/day, Holson et al. 2000). Exposure of rats by gavage to 26.6 mg As/kg/day as sodium arsenite, but not 13.3 mg As/kg/day or lower, 5 days/week for 4 weeks resulted in a significant decrease in body weight (Schulz et al. 2002). In 6-week rat studies, body weight gain was decreased at 11–12 mg As/kg/day, but not at 6–9 mg As/kg/day (Brown et al. 1976; Fowler et al. 1977). In a 12-week oral

gavage study, rats dosed with 1.5 mg/kg/day sodium arsenite had a median final body weight 18% lower than controls Dhar et al. (2005). A 60-day rat study with sodium arsenite in the drinking water reported a 13% reduction in final body weight in rats dosed with approximately 0.02 mg As/kg/day (Bashir et al. 2006). In chronic rat studies of arsenate and arsenite, body growth decreases were found at doses as low as 2 mg As/kg/day in feeding studies (Byron et al. 1967; Kroes et al. 1974), while rats exposed to lower levels of sodium arsenite in the drinking water (0.6 mg As/kg/day) throughout their lifetimes grew normally (Schroeder et al. 1968). Rats given a single oral dose of 100 mg As/kg as GaAs exhibited a 15% reduction in body weight compared to controls 7 days after exposure (Flora et al. 1998). Body weight gain was decreased in mice at 24 mg As/kg/day in a gestation exposure study (Nemec et al. 1998), 10 mg As/kg/day in a 6-week study (Fowler and Woods 1979), and 1 mg As/kg/day in a 2-year study (Schroeder and Balassa 1967). Growth was unaffected in mice that received 12 mg As/kg/day in the gestation exposure study (Nemec et al. 1998), 5 mg As/kg/day in the 6-week study (Fowler and Woods 1979), or 0.7–0.8 mg As/kg/day in 1–3 month arsenate drinking water studies (Healy et al. 1998). Dogs chronically treated with 2.4 mg As/kg/day as sodium arsenite lost 44–61% of their starting body weight and died, while lower doses had no effect on growth (Byron et al. 1967). Weight depression was also reported in dogs chronically treated with 2.4 mg As/kg/day as sodium arsenate (Byron et al. 1967). Feed consumption and body weight gain were significantly reduced in a dose-related manner in dogs fed 1.5 or 1.9 mg As/kg/day as sodium arsenite in the diet (Neiger and Osweiler 1989). Dogs in the high-dose group lost 25% of their body weight over the 17-week study period. Pair-fed controls lost weight at the same rate as high-dose dogs, showing that the effect on body weight was due to reduced feed consumption, rather than a direct effect of arsenic.

Organic Arsenicals. No studies were located regarding body weight effects in humans after oral exposure to organic arsenicals. In animal studies of organic arsenicals, decreases in body weight gain were observed in rats and mice after acute, intermediate, and chronic duration exposure to MMA (Arnold et al. 2003; Waner and Nyska 1988), DMA (Murai et al. 1993), and roxarsone (NTP 1989b); decreases in body weight gain have also been reported in pregnant rats and rabbits exposed to MMA (Irvine et al. 2006) or DMA (Irvine et al. 2006; Rogers et al. 1981). For MMA, the decreases in body weight gain were observed following intermediate-duration exposure of rats and dogs to 106.9 or 8 mg MMA/kg/day (Arnold et al. 2003; Waner and Nyska 1988), respectively, and following chronic-duration exposure of rats, mice, and dogs to 25.7, 67.1, or 8 mg MMA/kg/day, respectively (Arnold et al. 2003; Waner and Nyska 1988). The decreases in body weight gain occurred at doses that were associated with diarrhea and histological alterations in the gastrointestinal tract (Arnold et al. 2003; Waner and Nyska 1988). One DMA study in nonpregnant animals reported decreases in body weight gain in rats administered 57 mg

DMA/kg/day via gavage 5 days/week for 4 weeks (Murai et al. 1993); other DMA studies have not reported decreases in body weight gain in rats following exposure to 11 mg DMA/kg/day for acute durations (Cohen et al. 2001), 3.7–60 mg DMA/kg/day for intermediate durations (Arnold et al. 1999; Crown et al. 1987; Rubin et al. 1989; Siewicki 1981; Wanibuchi et al. 1996; Yamamoto et al. 1995), or 0.77 mg DMA/kg/day for chronic durations (Arnold et al. 2006). No alterations in body weight gain were observed in mice exposed to 94 mg DMA/kg/day for 2 years (Arnold et al. 2006). The lowest doses of roxarsone to produce a decrease in growth were 32 and 16 mg/kg/day in rats following acute- or intermediate-duration exposure, respectively, and 168 and 136 mg/kg/day in mice following acute or intermediate exposure (NTP 1989b); at the highest dose tested in chronic studies, no significant alterations in body weight gain were observed in rats at 4 mg/kg/day or in mice at 43 mg/kg/day (NTP 1989b).

3.2.2.3 Immunological and Lymphoreticular Effects

Inorganic Arsenicals. No studies were located regarding immunological and lymphoreticular effects in humans after oral exposure to inorganic arsenicals. No evidence of immunosuppression was detected in mice exposed to arsenate at levels up to 100 ppm (20 mg As/kg/day) in drinking water (Kerkvliet et al. 1980). This NOAEL is shown in Table 3-3 and Figure 3-3. Gallium arsenide at doses of 52–260 mg As/kg/day produced significant, dose-related decreases in relative spleen weight, spleen cellularity, humoral immune response (antibody forming cell response to sheep RBC), and delayed type hypersensitivity in rats (Flora et al. 1998). However, it is not clear to what extent these effects are due to the arsenic moiety.

Organic Arsenicals. No studies were located regarding immunological and lymphoreticular effects in humans or animals after oral exposure to organic arsenicals. No histological alterations were observed in immunological or lymphoreticular tissues following intermediate-duration exposure of rats to 43.2 mg DMA/kg/day in the diet (Crown et al. 1987) or rats and mice to 18.23 or 38.7 mg As/kg/day as roxarsone, respectively (NTP 1989b) or following chronic-duration exposure of rats and mice to 72.4 or 67.1 mg MMA/kg/day (Arnold et al. 2003), 7.8 or 94 mg DMA/kg/day (Arnold et al. 2006), or 4 or 43 mg/kg/day roxarsone (NTP 1989b). No studies examined immune function following oral exposure to organic arsenicals.

3.2.2.4 Neurological Effects

Inorganic Arsenicals. A large number of epidemiological studies and case reports indicate that ingestion of inorganic arsenic can cause injury to the nervous system. Acute, high-dose exposures (2 mg As/kg/day or above) often lead to encephalopathy, with signs and symptoms such as headache, lethargy, mental confusion, hallucination, seizures, and coma (Armstrong et al. 1984; Bartolome et al. 1999; Civantos et al. 1995; Cullen et al. 1995; Danan et al. 1984; Fincher and Koerker 1987; Levin-Scherz et al. 1987; Quatrehomme et al. 1992; Uede and Furukawa 2003; Vantroyen et al. 2004). Repeated exposures to lower levels (0.03–0.1 mg As/kg/day) are typically characterized by a symmetrical peripheral neuropathy (Chakraborti et al. 2003a, 2003b; Foy et al. 1992; Franzblau and Lilis 1989; Guha Mazumder et al. 1988; Hindmarsh et al. 1977; Huang et al. 1985; Lewis et al. 1999; Mizuta et al. 1956; Muzi et al. 2001; Silver and Wainman 1952; Szuler et al. 1979; Wagner et al. 1979). This neuropathy usually begins as numbness in the hands and feet, but later may develop into a painful "pins and needles" sensation. Both sensory and motor nerves are affected, and muscle weakness often develops, sometimes leading to wrist-drop or ankle-drop (Chhuttani et al. 1967; Heyman et al. 1956). Diminished sensitivity to stimulation and abnormal patellar reflexes have also been reported (Mizuta et al. 1956). Histological examination of nerves from affected individuals reveals a dying-back axonopathy with demyelination (Goebel et al. 1990; Hindmarsh and McCurdy 1986). Some recovery may occur following cessation of exposure, but this is a slow process and recovery is usually incomplete (Fincher and Koerker 1987; Le Quesne and McLeod 1977; Murphy et al. 1981). Peripheral neuropathy is also sometimes seen following acute high-dose exposures, with or without the previously described encephalopathy (Armstrong et al. 1984; Baker et al. 2005; Fincher and Koerker 1987; Goebel et al. 1990; Hantson et al. 1996; Kamijo et al. 1998). Neurological effects were not generally found in populations chronically exposed to doses of 0.006 mg As/kg/day or less (EPA 1981b; Harrington et al. 1978; Hindmarsh et al. 1977), although fatigue, headache, dizziness, insomnia, nightmare, and numbness of the extremities were among the symptoms reported at 0.005, but not 0.004 mg As/kg/day in a study of 31,141 inhabitants of 77 villages in Xinjiang, China (Lianfang and Jianzhong 1994), and depression was reported in some Wisconsin residents exposed to 2–10 μg As/L in the drinking water for 20 years or longer (Zierold et al. 2004).

There is emerging evidence suggesting that exposure to arsenic may be associated with intellectual deficits in children. For example, Wasserman et al. (2004) conducted a cross-sectional evaluation of intellectual function in 201 children 10 years of age whose parents were part of a larger cohort in Bangladesh. Intellectual function was measured using tests drawn from the Wechsler Intelligence Scale for Children; results were assessed by summing related items into Verbal, Performance, and Full-Scale

raw scores. The mean arsenic concentration in the water was 0.118 mg/L. The children were divided into four exposure groups, representing <5.5, 5.6–50, 50–176, or 177–790 µg As/L drinking water. After adjustment for confounding factors, a dose-related inverse effect of arsenic exposure was seen on both Performance and Full-Scale subset scores; for both end points, exposure to ≥50 µg/L resulted in statistically significant differences (p<0.05) relative to the lowest exposure group (<5.5 µg/L). In a later report, the same group of investigators examined 301 6-year-old children from the same area (Wasserman et al. 2007). In this case, the children were categorized into the following quartiles based on water arsenic concentration: 0.1–20.9, 21–77.9, 78–184.9, and 185–864 µg/L. After adjustment for water Mn, blood lead, and sociodemographic features known to contribute to intellectual function, water arsenic was significantly negatively associated with both Performance and Processing speed raw scores. Analyses of the dose-response showed that compared to the first quartile, those in the second and third categories had significantly lower Performance raw scores (p<0.03 and p=0.05, respectively). Those in the fourth category had marginally significantly lower Full-Scale and Processing Speed raw scores. It should be mentioned, however, that in general, arsenic in the water explained <1% of the variance in test scores. Water arsenic made no contribution to IQ outcomes. A study of 351 children age 5–15 years from West Bengal, India, found significant associations between urinary arsenic concentrations and reductions in scores of tests of vocabulary, object assembly, and picture completion; the magnitude of the reductions varied between 12 and 21% (von Ehrenstein et al. 2007). In this cohort, the average lifetime peak arsenic concentration in well water was 0.147 mg/L. However, no clear pattern was found for increasing categories of peak arsenic water concentrations since birth and children's scores in the various neurobehavioral tests conducted. Furthermore, using peak arsenic as a continuous variable in the regression models also did not support an adverse effect on the tests results. Exposure to arsenic *in utero* also did not suggest an association with the tests scores. Von Ehrestein et al. (2007) concluded that the study provided little evidence for an effect of long-term arsenic concentrations in drinking water and that the lack of findings with past exposures via drinking water may be due to incomplete assessment of past exposure, particularly exposure originating from food. Wasserman's results are consistent with those of ecological studies in children in Taiwan (Tsai et al. 2003) and in China (Wang et al. 2007). In the former, adolescents exposed to low (0.0017–0.0018 mg As/kg/day; n=20) levels of inorganic arsenic in the drinking water showed decreased performance in the switching attention task, while children in the high exposure group (0.0034–0.0042 mg As/kg/day; n=29) showed decreased performance in both the switching attention task and in tests of pattern memory, relative to unexposed controls (n=60). In the study in China (age 8– 12 years), 87 children whose mean arsenic concentration in the drinking water was 0.190 mg/L had a mean IQ score of 95 compared with 101 for children (n=253) with 0.142 mg/L arsenic in the water and 105 for control children (n=196) with 0.002 mg/L arsenic in the drinking water (Wang et

al. 2007). The differences in IQ scores between the two exposure groups and the control group were statistically significant.

Neurological effects have also been observed in animal studies. Rodriguez et al. (2001) evaluated neurobehavioral changes in male Sprague-Dawley rats exposed to 0, 5, 10, or 20 mg As/kg/day as sodium arsenite by gavage for 2 or 4 weeks; significant effects were seen in spontaneous locomotor activity and the food pellet manipulation test in the high-dose animals, while no effects were seen in the low- or mid-dose rats. Decreased performance in open field tests were also seen in rats exposed to 26.6 mg As/kg/day, but not to 13.3 mg/kg/day or less, as sodium arsenite for 4 weeks (Schulz et al. 2002); curiously, the behavioral changes were no longer present at 8 and 12 weeks of exposure, which may suggest an adaptive response. Heywood and Sortwell (1979) reported salivation and uncontrolled head shaking in two monkeys given several doses of 6 mg As/kg/day as arsenate, while no such effects were noted in monkeys given 3 mg As/kg/day for 2 weeks. Nemec et al. (1998) observed ataxia and prostration in pregnant female rabbits treated with 1.5 mg As/kg/day repeatedly during gestation, but not in rabbits treated with 0.4 mg As/kg/day. Some changes in levels of neurotransmitters (dopamine, norepinephrine, and 5-hydroxytryptamine) were seen in rats exposed to 2.3 mg As/kg/day as sodium arsenite and guinea pigs exposed to 1.7 mg As/kg/day as sodium arsenite in the drinking water for 16 weeks (Kannan et al. 2001) or in rats exposed to 0.14 mg As/kg/day as sodium arsenite by gavage for 28 days (Chattopadhyay et al. 2001), but the functional significance of these changes is not clear.

The highest NOAEL values and all reliable LOAEL values for neurological effects from inorganic arsenic in each species and duration category are recorded in Table 3-3 and plotted in Figure 3-3.
